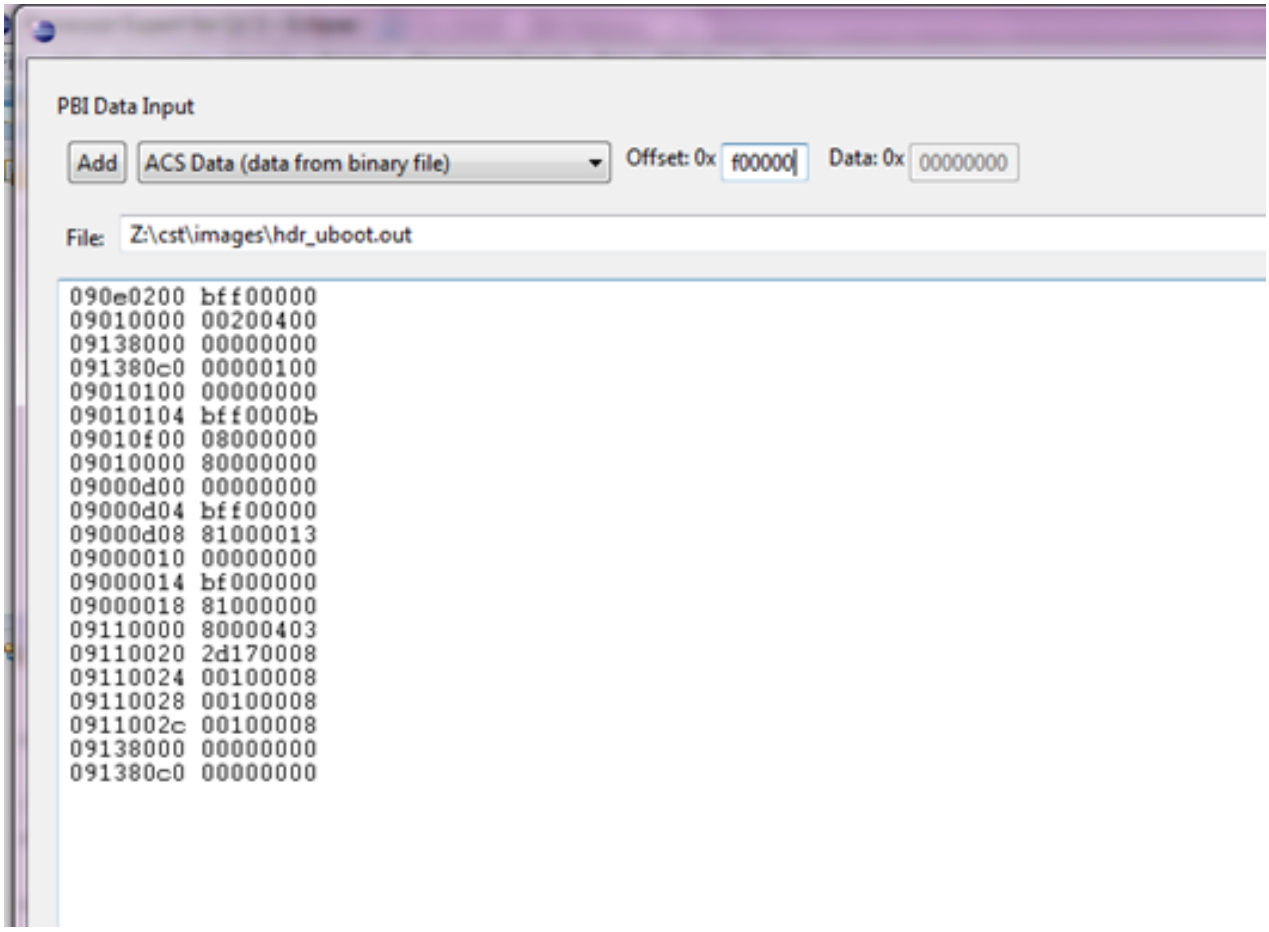
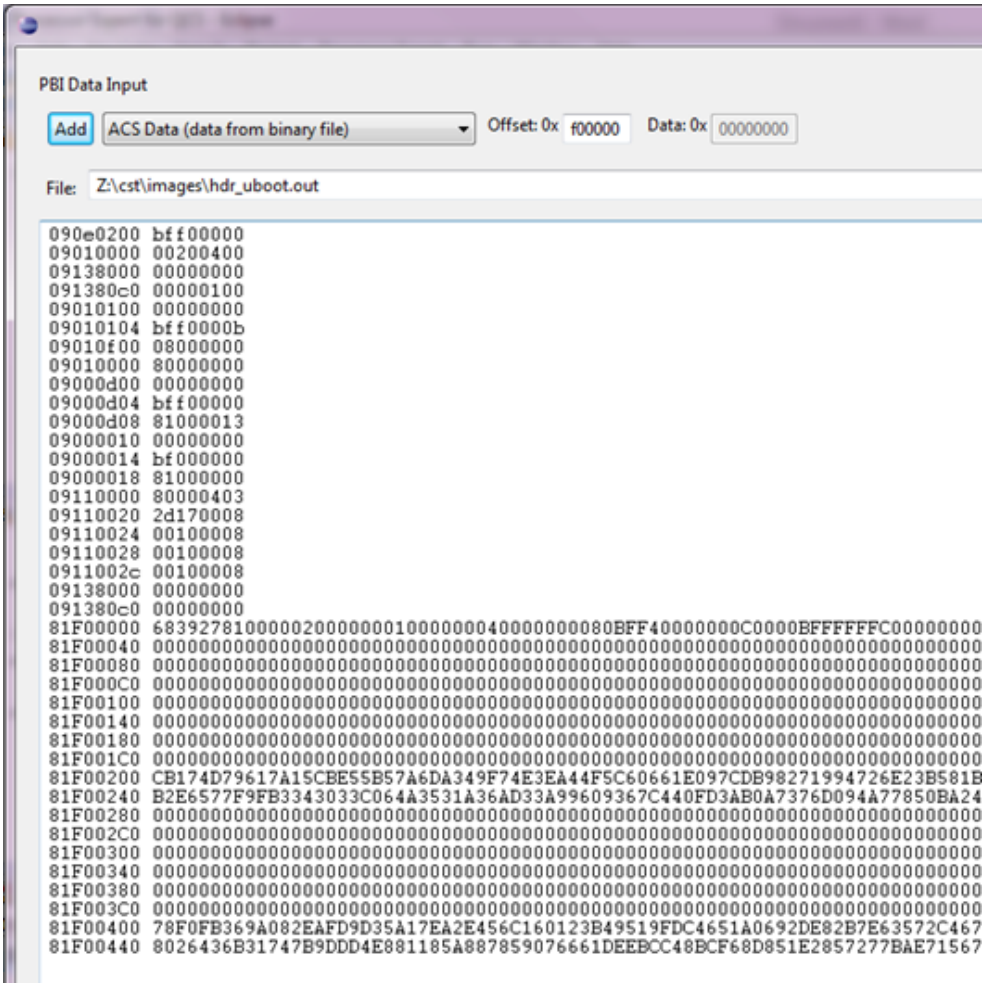
10.3.1.13 Using QCVS Tool (Secure Boot From NAND)

Use NXP's QCVS tool for adding the hdr_uboot.out and u-boot.bin in terms of ALT_CONFIG_WRITE PBI commands at required addresses. The below screenshots describe the usage of QCVS Tool.

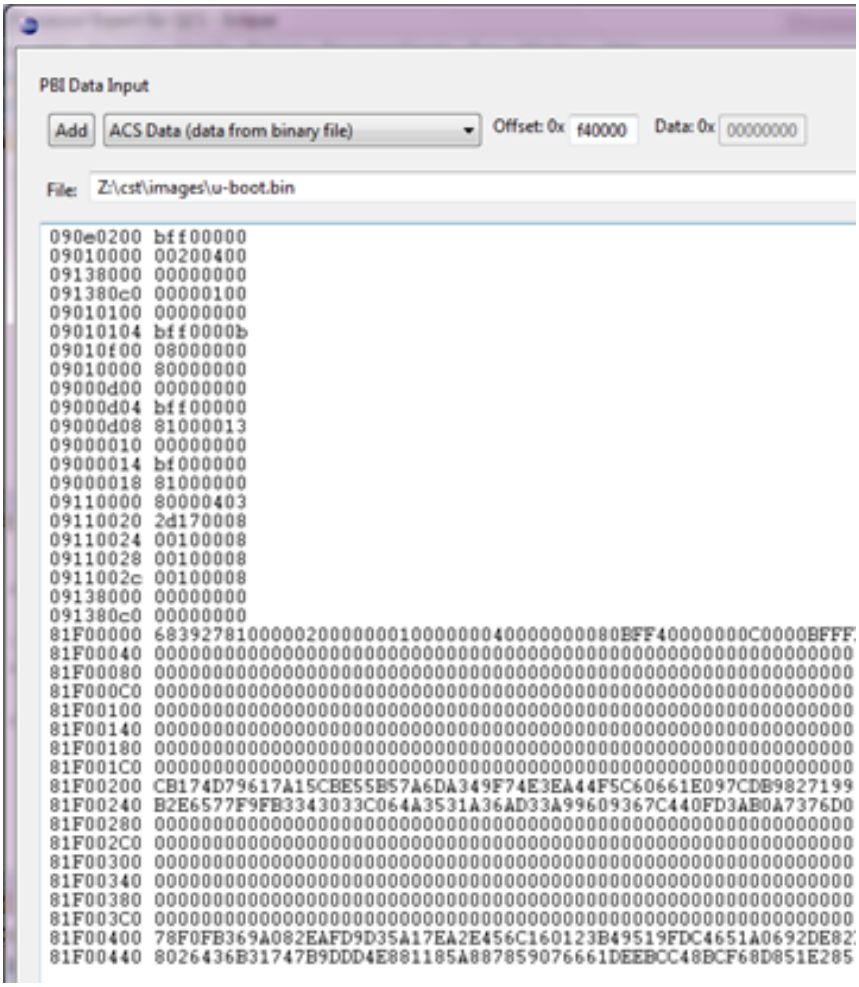
1. Import rcw.bin from SDK in QCVS Tool.
2. Add ACS Data hdr_uboot.out @ 0xF00000.



PBI Data Input
Add
ACS Data (data from binary file)
Offset: 0x f00000
Data: 0x 00000000
File: Z:\cst\images\hdr_uboot.out
090e0200 bff00000
09010000 00200400
09138000 00000000
091380c0 00000100
09010100 00000000
09010104 bff0000b
09010f00 08000000
09010000 80000000
09000d00 00000000
09000d04 bff00000
09000d08 81000013
09000010 00000000
09000014 bf000000
09000018 81000000
09110000 80000403
09110020 2d170008
09110024 00100008
09110028 00100008
0911002c 00100008
09138000 00000000
091380c0 00000000



3. Add ACS Data u-boot.bin @0xF40000.



PBI Data Input
Add
ACS Data (data from binary file)
Offset: 0x f40000
Data: 0x 00000000
File: Z:\cst\images\u-boot.bin
090e0200 bff00000

10.3.1.16 Appendix LS1012 Secure Boot demo

Boot Source

Table 337. Memory map for LS1012 platform

Address QSPI[23]	Definition (Chain of Trust)	Size Reserved (KB)
40000000	RCW	128
40060000	Bootscript	128
40080000	ESBC U-Boot HEADER	128
400C0000	Bootscript Header	128
40100000	PPA Header	128
40480000	ESBC U-Boot	1024
40500000	PPA FIT Image	2048
40A00000[24]	Kernel FIT Image	54272
43200000	kernel Header	128

[23] QSPI by default works in 64bit Big Endian as XIP memory. So the data has to be 64 bit byte swapped before loading on QSPI.
[24] The Kernel Image and its CSF Header may be placed on any other memory as well. The same must be copied to DDR before validation and Booting.

Chain of Trust Boot Script Used as per Address Map

```
#Copy the Kernel Image from Flash to DDR
cp.b 0x40A00000 0xa0000000 0x2800000
#Validate the Kernel Image (The header has Image address as 0x81000000)
esbc_validate 0x43200000
#Boot the validated Kernel FIT Image.
setenv bootargs "console=ttyS0,115200 root=/dev/ram0 earlycon=uart8250,0x21c0500";
setenv fdt_high "0xffffffffffffffff";
setenv initrd_high "0xffffffffffffffff";
bootm 0xa0000000
```

Refer to the ‘Product Execution’ section and blow the required fuses as mentioned in it before executing the following commands

Useful U-Boot and CCS Commands

```
protect off all;
setenv path <tftp_path>
sf probe 0:0

10.3.2 Software-PreBoot Loader (PBL) Based Platforms

10.3.2.1 Introduction

This document is intended for end-users to demonstrate the image validation process. The image validation can be split into stages, where each stage performs a specific function and validates the subsequent stage before passing control to that stage. In the example, the ESBC is NXP provided reference code referred to as ESBC uboot.

Chain of Trust ESBC uboot performs minimal SoC configuration before validating the Next Executable using the same CSF header format as the ISBC used to validate ESBC Uboot. The CSF Header and signature are added to the Next Executable using the NXP Code Signing Tool.

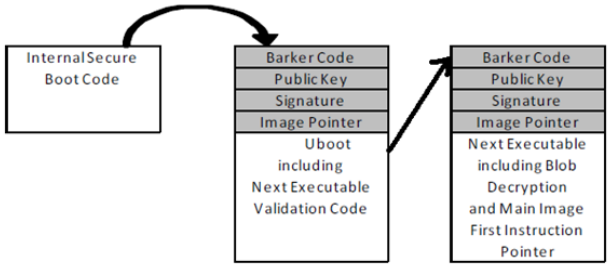

Figure 322. Chain of Trust

Chain of Trust with confidentiality

The validated ESBC uboot image is allowed to use the One Time Programmable Master Key to decrypt system secrets. Cryptographic blob mechanism is used to establish Chain of trust with confidentiality.

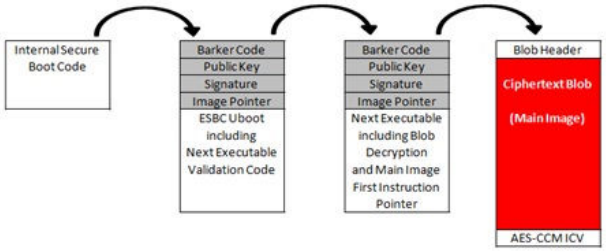

Figure 323. Chain of Trust with confidentiality

This document provides more details on the secure boot flow, ISBC, ESBC and NXP Code signing tool.

10.3.2.2 Image Signing

10.3.2.2.1 Overview

This document describes how to use secure boot capability in non-pbl platforms. The QorIQ platforms are cost-effective, low-power, highly integrated host processor that addresses the requirements of several routing, gateways, storage, consumer, and industrial applications. It does not incorporate the PreBoot Loader hardware.

Non-PBL platform supports two booting modes namely trusted or secure boot and legacy/non-secure boot.

Trusted mode — Boot images are validated against a digital signature before executing. The trusted mode gives a benefit that only OEM's signed boot images can be executed on these SOCs.

Legacy boot/non-secure boot — Booting happens from various boot targets as supported by SOC. SD/SDHC/MMC and SPI boot methods are supported using Internal Boot ROM.

When the device is first powered on, reset control logic blocks all device activity (including scan and debug activity) until fuse values can be accurately sensed. The most important fuse value at this stage of operation is the intent to secure (ITS) bit. If the user sets ITS, they intend for the system to operate in a secure and trusted manner. The setting of ITS determines the default settings of a range of configuration registers within the device, essentially locking down interfaces, memory permissions, and MMU configurations until trusted software is executing.

If the user sets the ITS bit, it is intended that the system operates in a secure and trusted manner. To ensure this, after the ITS bit is set, the system jumps to an internal secure ROM for booting, regardless of the value provided in the boot location POR. When execution begins from the IBR, it checks the cfg_rom_loc value that indicates the source of external secure boot code location. The value provided in the cfg_rom_loc directs the IBR to configure the respective peripheral.

If the user doesn't want to fuse the ITS bit, he can set CFG_SB_DIS to 0 to pass the system control to IBR.

The task of the IBR is to determine if subsequent code (referred to as the External Secure Boot Code, or ESBC) is valid before allowing that code to execute. To perform this validation, the IBR needs the information described in the following subsections.

10.3.2.2.2 ESBC with CF Header and CSF Header

ESBC is the generic name for the code that the ISBC validates. A few ESBC scenarios are described in later sections.

The I2C boot sequencer provides a way to configure the system using a set of address data tuples stored in I2C EEPROM. The boot sequencer works only in the legacy mode. In the secure mode the boot sequencer is disabled. However the same functionality is achieved by adding a similar data structure called a CF header or a configuration header. This header is on the lines of the SD/MMC and eSPI data structure containing the control words and configuration words. IBR running on the core first authenticates the CF Header and then executes the configuration words.

Figures below provide an example of an ESBC with CF header and CSF (Command Sequence File) Header prepended to it. The CF Header contains legacy mode fields, configuration words to initialize destination interfaces like DDR, ESBC header pointer. The CSF Header includes lengths and offset which allow the IBR to locate the operands used in ESBC image validation, as well as describe the size and location of the ESBC image itself.

NOTE

CSF Header and ESBC Header may be used synonymously in this and other NXP Trust Architecture documentation.

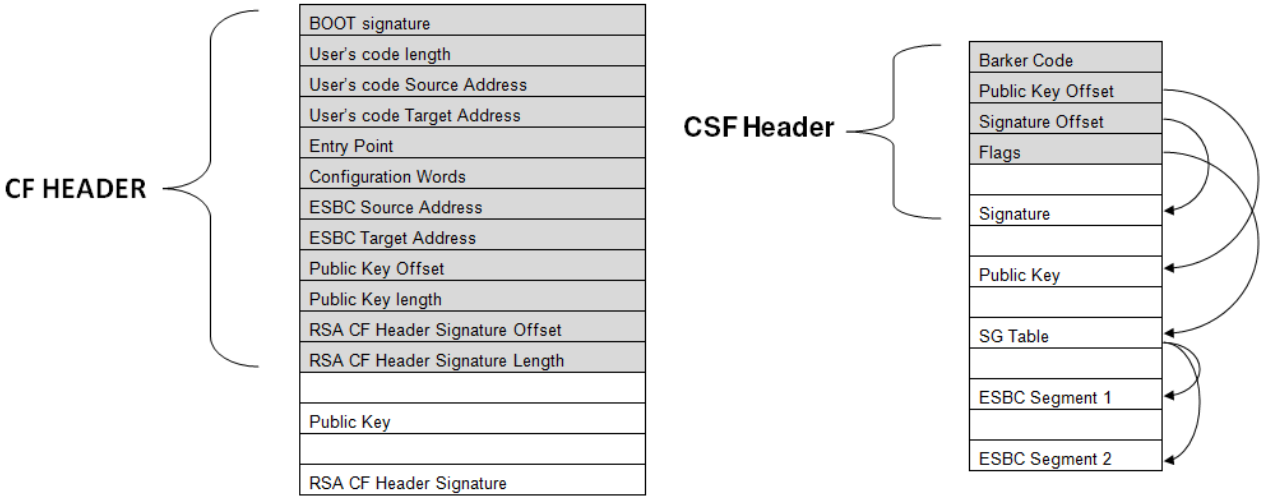

Figure 324. ESBC with CF and CSF Header for P1010/9131/9132

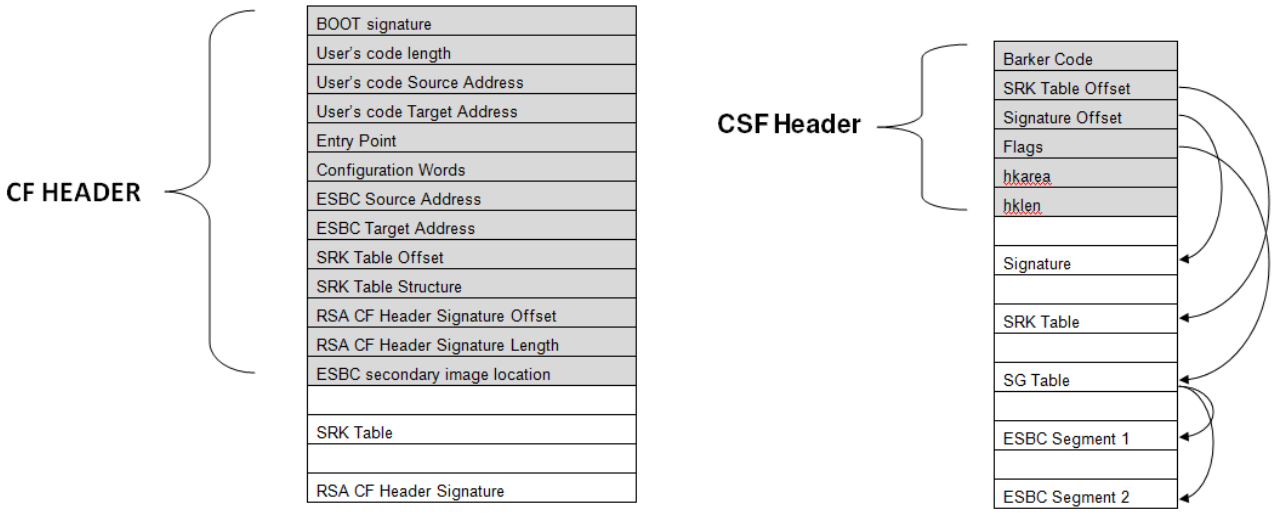

Figure 325. ESBC with CF and CSF Header for C290

10.3.2.3 Image validation

Although the CF Header and CSF Header provide most of the information needed for the IBR to perform image validation, the IBR can't begin until it finds the CF Header. The ISBC gets the CF Header pointer from 0th location of the 0th sector on the target interface. The fixed value Boot Signature (0x424f4f54) at the 0x40 offset from the start of the CF Header allows the ISBC to know it has found a CF Header. If the ISBC doesn't find the Boot Signature at the CF Header 0x40 location, the ISBC reports an error and shuts down. See Validation Failures from ISBC on page 2024 for more information on validation failures.

10.3.2.3.1 Validation failures

Validation failure can occurs at 2 stages:

1. ISBC fails to validate CF header or ESBC header
2. ESBC fails to validate the next level executable

The section below describes the details of these validation failures.

10.3.2.3.1.1 Validation Failures from ISBC

There are many reasons the IBR could fail to validate the ESBC. Technicians with debug access can check the GUTS SBDCR (CCSRBAR + 0xe0f90) register to obtain an error code.

For a list of error codes refer ISBC Validation Error Codes on page 2057

10.3.2.3.1.2 Validation Failures from ESBC

There are many reasons ESBC could fail to validate Client images or boot script. The error status message along with the code is printed on the u-boot console.

Table 348. ESBC Validation Failures

Value	Code	Definition
0x4	ERROR_ESBC_CLIENT_HEADER_BARKER	Wrong barker code in header

Table continues on the next page...

Table 348. ESBC Validation Failures (continued)

Value	Code	Definition
0x8	ERROR_ESBC_CLIENT_HEADER_KEY_LEN	Wrong public key length in header
0x10	ERROR_ESBC_CLIENT_HEADER_SIG_LEN	Wrong signature length in header
0x20	ERROR_ESBC_CLIENT_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Public key length not twice of signature length
0x40	ERROR_ESBC_CLIENT_HEADER_KEY_MOD_1	Public key Modulus most significant bit not set
0x80	ERROR_ESBC_CLIENT_HEADER_KEY_MOD_2	Public key Modulus in header not odd
0x100	ERROR_ESBC_CLIENT_HEADER_SIG_KEY_MOD	Signature not less than modulus
0x400	ERROR_ESBC_CLIENT_HASH_COMPARE_KEY	Public key hash comparison failed
0x800	ERROR_ESBC_CLIENT_HASH_COMPARE_EM	RSA verification failed
0x10000	ERROR_ESBC_CLIENT_HEADER_SG	No SG support
0x20000	ERROR_ESBC_WRONG_CMD	Failure in command/Unknown command/Wrong arguments of boot script.
0x40000	ERROR_ESBC_MISSING_BOOTM	Bootm command missing from boot script.

10.3.2.3.2 Boot script

Bootscript is a U-Boot script image which contains u-boot commands. ESBC would validate this boot script before executing commands in it.

NOTE

1. Boot script can have any commands which u-boot supports. No checking on the allowed commands in boot script. Since it is validated image, assumption is that commands in boot script would be correct.
2. If some basic scripting error done in boot script like unknown command, missing arguments, the required usage of that command and core is put in infinite loop.
3. After execution of commands in boot script, if control reaches back in u-boot, error message would be printed on u-boot console and core would be put in spin loop by command esbc_halt.
4. Scatter gather images not supported with validate command.
5. If ITS fuse is blown, any error in verification of the image would result in system reset. The error would be printed on console before system goes for a reset.

10.3.2.3.2.1 Where to place the boot script?

NXP's ESBC u-boot expects the boot script to be loaded in flash as specified in Address map used for the demo on page 2064. ESBC u-boot code assumes that the public/private key pair used to sign the boot script is same as that was used while signing the u-boot image. If user used different key pair to sign the image, hash of the N and E component of the key pair should be defined in macro:

CONFIG_BOOTSCRIPT_KEY_HASH.

Note - The hash defined should be hex value, 256 bits long.

Both the above macros can be defined or changed in the configuration file secure_boot.h at the following location in u-boot code:

```
u-boot/arch/powerpc//include/asm/fsl_secure_boot.h
```

Two new commands called esbc_validate and esbc_halt have been added in NXP ESBC u-boot.

10.3.2.3.3 What is ESBC?

Depending on the requirement, ESBC can be a monolithic image - including uboot, device trees, boot firmware, drivers along with the OS and applications or can be mini-uboot.

NXP provided ESBC consists of standard u-boot which has been signed using a private key. U-boot reserves a small space for storing environment variables. This space is typically one sector above or below the u-boot and is stored on persistent storage devices like NOR flash if macro CONFIG_ENV_IS_IN_FLASH is used. In case of secure boot, macro CONFIG_ENV_IS_NOWHERE is used and so, environment is compiled in uboot image and is called default environment. This default environment can't be stored on flash devices. User won't be able to edit this environment also as he can't reach to uboot prompt in case of secure boot. There is default boot command for secure boot in this default environment which executes on autoboot.

ESBC validates a file called boot script and on successful validation execute the commands in the boot script.

Users are free to use NXP ESBC as it is provided or to use it as reference to modify their own secure boot system.

10.3.2.3.3.1 Chain of Trust

Boot script contains information about the next level of images, e.g. Linux, HV, etc. ESBC validates these images as per their public keys and then executes bootm command to pass-on the control to next image.

Users are free to use NXP ESBC as it is provided or to use it as reference to modify their own secure boot system.

Figure below shows the Chain of trust established for Validation with this ESBC u-boot.

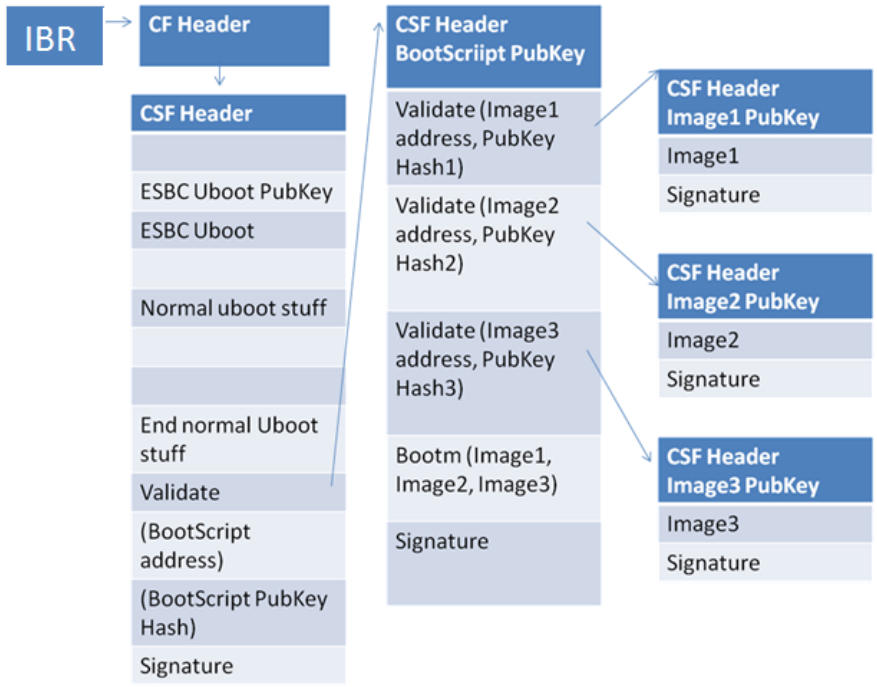

Figure 326. Secure boot flow (Chain of Trust)

10.3.2.3.3.1.1 Sample Boot Script

A sample boot script would look like:

```
...
esbc_validate <Img1 header addr> <pub_key hash>
esbc_validate <Img2 header addr> <pub_key hash>
esbc_validate <Img3 header addr> <pub_key hash>
...
bootm <img1 addr> <img2 addr> <img3 addr>
```

10.3.2.3.3.1.1.1 esbc_validate command

esbc_validate img_hdr [pub_key_hash]

Input arguments:

`img_hdr` - Location of CSF Header of the image to be validated

`pub_key_hash` - hash of the public key used to verify the image. This is optional parameter. If not provided, code makes the assumption that the key pair used to sign the image is same as that used with ISBC. So the hash of the key in the header is checked against the hash available in SRK fuse for verification.

Description:

The command would do the following:

- Perform CSF header validation on the address passed in the image header. During parsing of the header, image address in stored in an environment variable which is later used in source command in default secure boot command.
- Signature checks on the image

10.3.2.3.3.1.1.2 esbc_halt command

esbc_halt (no arguments)

Description:

The command would do the following:

This command puts core in spin loop.

After successful validation of images, bootm command in bootscript should execute and control should never reach back to uboot. If somehow, control reaches back to uboot (eg. bootm not present in bootscript), core should just spin.

10.3.2.3.3.2 Chain of Trust with Confidentiality

To establish chain of trust with confidentiality, cryptgraphic blob mechanism can be used. In this chain of trust, validated image is allowed to use the One Time Programmable Master Key to decrypt system secrets.

Two bootscripts are to be used. First encap bootscripts is used which creates a blob of the LINUX images and saves them. After this the system is booted after replacing the encap bootscript with decap bootscript which decapsulates the blobs and boot the LINUX with the images.

Figures below show the Chain of trust with confidentiality (Encapsulation and Decapsulation).

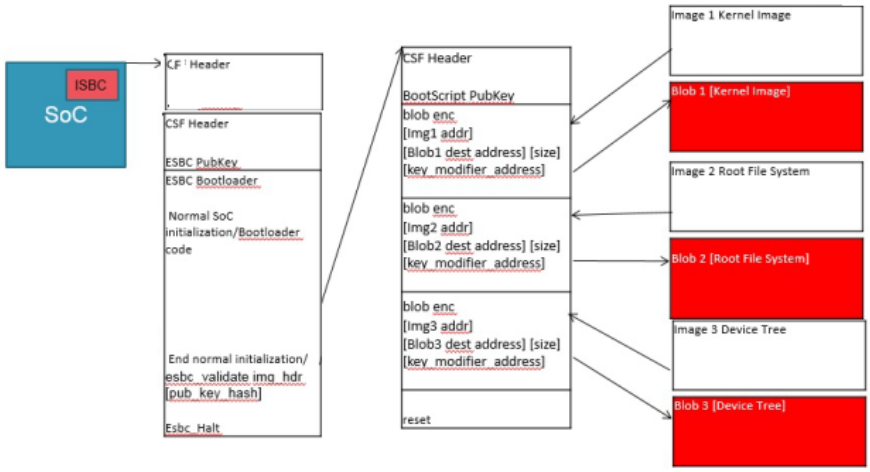

Figure 327. Chain of Trust with Confidentiality (Encapsulation)

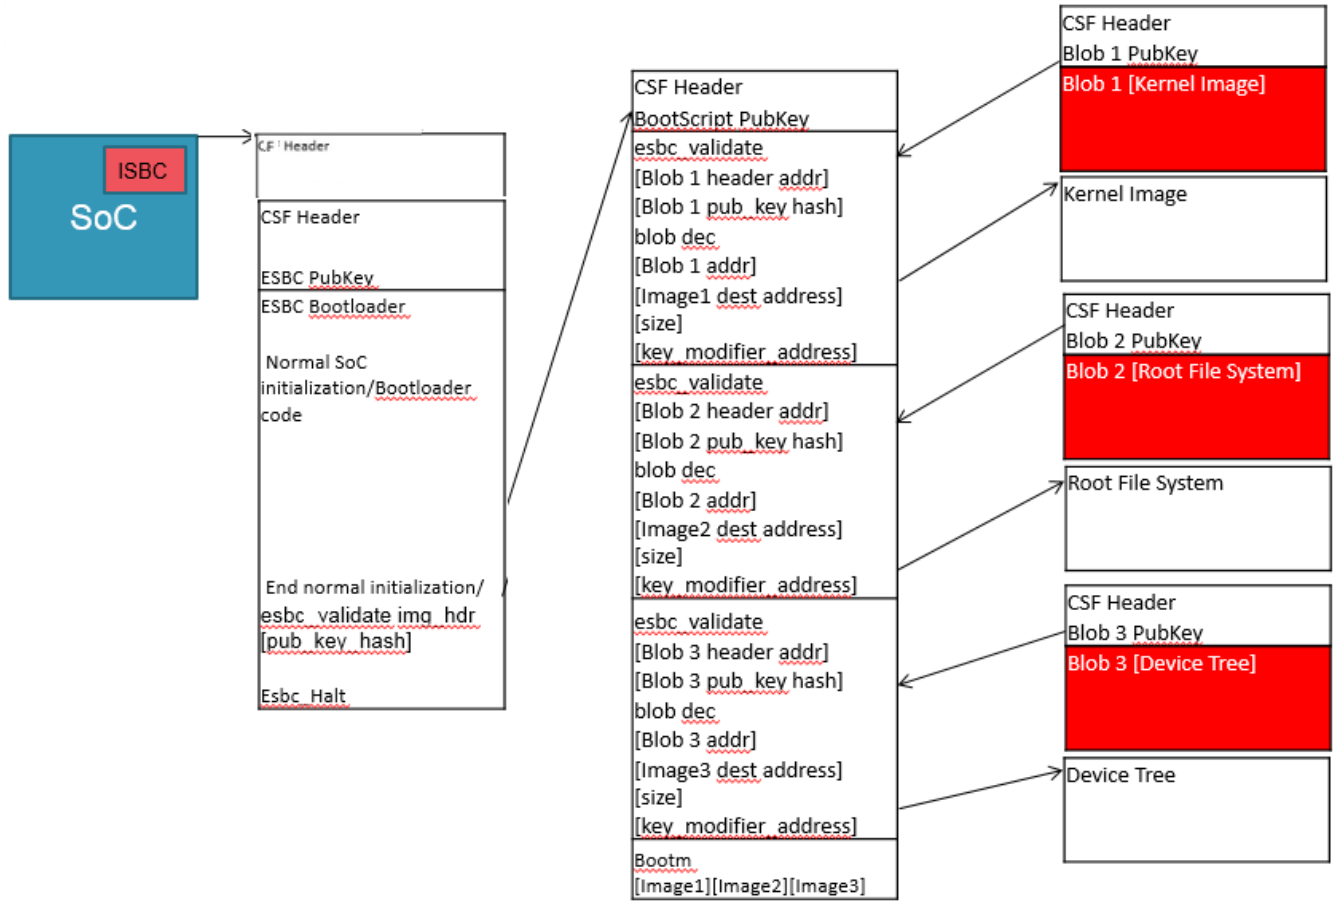

Figure 328. Chain of Trust with Confidentiality (Decapsulation)

10.3.2.3.3.2.1 Sample Encap Boot Script

A sample encap boot script would look like:

```
...
blob enc <Img1 addr> <Img1 dest addr> <Img1 size> <16byte key modifier address>
erase <encap Img1 addr> +<Img1 size + 0x30>
cp.b <Img1 dest addr> <encap Img1 addr> <Img1 size + 0x30>

blob enc <Img2 addr> <Img2 dest addr> <Img2 size> <16byte key modifier address>
erase <encap Img2 addr> +<Img2 size + 0x30>
cp.b <Img2 dest addr> <encap Img2 addr> <Img2 size + 0x30>

blob enc <Img3 addr> <Img3 dest addr> <Img3 size> <16byte key modifier address>
erase <encap Img3 addr> +<Img3 size + 0x30>
cp.b <Img3 dest addr> <encap Img3 addr> <Img3 size + 0x30>

...
```

10.3.2.3.3.2.1.1 blob enc command

blob enc <src location> <dst location> <length> <16 byte key modifier address>

Input arguments:

`src location` - Address of the image to be encapsulated

`dst location` - Address where the blob will be created

`length` - Size of the image to be encapsulated

`key modifier address` - Address of any 16 bytes long random number

Description:

The command would do the following:

- Create a cryptographic blob of the image placed at src location and place the blob at dst location.

10.3.2.3.3.2.2 Sample Decap Boot Script

A sample decap boot script would look like:

```
...
blob dec <Img1 blob addr> <Img1 dest addr> <Img1 size + 0x30> <16byte key modifier address>
blob dec <Img2 blob addr> <Img2 dest addr> <Img2 size + 0x30> <16byte key modifier address>
blob dec <Img3 blob addr> <Img3 dest addr> <Img3 size + 0x30> <16byte key modifier address>
...
bootm <Img1 dest addr> <Img2 dest addr> <Img3 dest addr>
```

10.3.2.3.3.2.2.1 blob dec command

blob dec <src location> <dst location> <length> <16 byte key modifier address>

Input arguments:

`src location` - Address of the image blob to be decapsulated

`dst location` - Address where the decapsulated image will be placed

`length` - Expected Size of the image after decapsulation.

`key modifier` - Address of any 16 bytes long random number(Same as that used for Encapsulation)

Description:

The command would do the following:

- Decapsulate the blob placed at src location and place the decapsulated data of expected size at dst location.

10.3.2.4 Product execution

This section presents the steps needed to be followed in order to properly run the software product according to its intended use and functionalities.

10.3.2.4.1 Getting started

In the demo we map the flash to the following addresses for the ISBC code to validate ESBC in NOR Flash using configuration words in CF Header.

- P1010 : 0xce000000
- BSC9131 : 0xce000000
- BSC9132 : 0xc8000000
- C290: 0xcc000000

Once the control reaches the ESBC code the earlier mapping of flash is removed and flash is mapped to address based on the platform as specified in .

NOTE

- ISBC expects the code to be validated i.e. ESBC code to be within **0 – 3.5G** address map.
- It is recommended not to create any LAW using CF words in CF Header at LAW 0 before U-boot. As ISBC creates a LAW 0 entry for nor and nand which will be removed in U-boot startup code.

The example below demonstrates the secure-boot flow with all the images loaded in NOR Flash.

10.3.2.4.1.1 SDK Images required for the demo

Given below are the images required for the demo which are built with Yocto as part of the SDK:

1. ESBC (U-Boot)
2. uImage (Linux Image)
3. rootfs Image
4. Device tree

Please refer to User Manual QorIQ DPAA SDK for detailed description on how to run Yocto Build. Once the build process finishes, all the binaries would be present at the following location:

build_<platform>_release/tmp/deploy/images

The images will be created with the following names:

u-boot-<platform>.bin	U-Boot binary image for Secure Boot
uImage-<platform>.bin	kernel image that can be loaded with U-Boot
fsl-image-core-<platform>.ext2.gz.u-boot	ramdisk filesystem image that can be loaded with U-Boot
uImage-<platform>.dtb	device tree binary(dtb) for kernel bootup

10.3.2.4.2 Chain of Trust

This section presents the steps needed to be followed in order to execute Chain of Trust.

Steps in the demo would be:

1. ISBC code would validate the ESBC code.
2. On successful validation, ESBC code would run, which would then validate the boot script.
3. On successful validation of boot script, commands in boot script would be executed.
4. The boot script contains commands to validate next level images, i.e rootfs, linux uImage and device tree.
5. Once all the images are validated, bootm command in boot script would be executed which would pass control to linux.

10.3.2.4.2.1 Other images required for the demo

Apart from SDK images described above, the following images are also required:

1. CF header of the ESBC u-boot image
2. CSF Header of the ESBC u-boot image
3. CSF Header of the uImage
4. CSF Header of the rootfs image
5. CSF Header of the device tree
6. Boot Script
7. CSF Header of the boot script

The following section describes how to create the CF header, CSF headers and boot script.

10.3.2.4.2.2 Boot Script and Signing the images

User can sign all the images with same public/private key pair or can use different key pairs to sign the images. Section below describes both the processes.

CST tool used for signing the images is provided as a package with yocto and is built for host. It can be run from your host machine.

Install path for CST binaries in yocto:

```
tmp/sysroots/x86_64-linux/usr/bin/cst/
```

CST uses openssl libraries, version 0.9.8.

In the Yocto environment, the user needs to use below commands to rebuild cst:

1. bitbake cst-native –c cleanall
2. bitbake cst-native
3. Modify the CST source code if needed.
4. bitbake cst-native –c cleanall
5. bitbake cst-native –c patch

Note: after step5, CST binary will be put to build_<platform>_release/tmp/sysroots/x86_64-linux/usr/bin/cst/ directory.

10.3.2.4.2.2.1 Signing the images using same key pair

CSF header needs to be generated for all the images. More details on the commands provided by CST can be found in Section .

1. Generate the key pair to be used for signing the image

   ```
   ./gen_keys 1024
   ```

   Key pair - public key file - srk.pub and private key in srk.priv would be generated.

2. Obtain hash string of the key pair generated to be programmed in SFP

   ```
   ./uni_sign --hash input_files/uni_sign/<platform>/input_uboot_secure
   ```

   This would provide you the 256 bit hash in form of string of the key pair generated in the previous step. The hash has to be programmed in the SRK hash Fuse.

3. Create CF header for u-boot Image.

   ```
   ./uni_cfsign input_files/uni_cfsign/<platform>/input_<device>_secure
   ```

   The input fields are specified in input_<device>_secure file. Please ensure that the filename mentioned in the input_<device>_secure is same as copied in the cst directory.

4. Create CSF header for u-boot Image.

   ```
   ./uni_sign input_files/uni_sign/<platform>/input_uboot_secure
   ```

   The input fields are specified in input_uboot_secure file. Please ensure that the filename mentioned in the input_uboot_secure is same as copied in the cst directory.

5. Create CSF header for Linux uImage

   ./uni_sign input_files/uni_sign/<platform>/input_uimage_secure

   uImage.bin would be validated form u-boot. The flash address used here is according to the address map of u-boot. Please ensure that filename mentioned in the input_uimage_secure is same as copied in the cst directory.

6. Create CSF header for rootfs

   ```
   ./uni_sign input_files/uni_sign/<platform>/input_rootfs_secure
   ```

```
Please make sure that filename mentioned in the input_rootfs_secure is same as copied in the cst
directory
```

7. Create CSF Header for hardware device tree

   ```
   ./uni_sign input_files/uni_sign/<platform>/input_dtb_secure
   ```

   ```
   Please make sure that filename mentioned in the input_dtb_secure is same as copied in the cst
   directory
   ```

8. Create Boot script

   Bootscript is a U-Boot script image. Steps to create bootscript are given below :

   a. Create a text file bootscript.txt with following commands.

   ```
   esbc_validate <uImage CSF Header address>

   esbc_validate <dtb CSF Header address>

   esbc_validate <rootfs CSF Header address>

   bootm <uImage Address> <rootfs address> <dtb address>
   ```

   b. Then you will have to use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

   ```
   /tmp/sysroots/x86_64-linux/usr/bin/mkimage -A ppc -T script -a 0 -e 0x40 -d bootscript.txt
   bootscript
   ```

9. Generate CSF hdr for the boot script

   ./uni_sign input_files/uni_sign/<platform>/input_bootscript_secure

   The fields can be changed in the input files for the images based on the requirement.

10.3.2.4.2.2.2 Signing the images using different key pair

If boot script is also signed with a different key, remember to define the macro "**CONFIG_BOOTSCRIPT_KEY_HASH**" with the hash of the key used to sign the boot script in file *arch/powerpc/asm/include/fsl_secure_boot.h*. *ESBC u-boot would have to be recompiled if any change in this file is made*.

1. Generate the key pair to be used for signing the image

   ```
   ./gen_keys 1024 -p u-boot.priv -k u-boot.pub
   ```

   Key pair - public key file - u-boot.pub and private key in u-boot.priv would be generated.

2. Obtain hash string of the key pair generated to be programmed in SFP

   ```
   ./uni_sign --hash input_files/uni_sign/<platform>/input_uboot_secure
   ```

   This would provide you the 256 bit hash in form of string of the key pair generated in the previous step. The hash has to be programmed in the SRK hash Fuse.

3. Create CF header for u-boot Image.

   Open input_files/uni_cfsign/<platform>/input_<device>_secure and change PRI_KEY and PUB_KEY to u-boot.priv and u-boot.pub respectively and run the following command

   ```
   ./uni_cfsign input_files/uni_cfsign/<platform>/input_<device>_secure
   ```

4. Create CSF header for u-boot Image.

   Open input_files/uni_sign/<platform>/input_uboot_secure and change PRI_KEY and PUB_KEY to u-boot.priv and u-boot.pub respectively and run the following command

   ```
   ./uni_sign input_files/uni_sign/<platform>/input_uboot_secure
   ```

5. Create CSF header for Linux uImage using different key pair.

   Repeat step 1 to generate another key pair.

   ```
   ./gen_keys 1024 -p lnx.priv -k lnx.pub
   ```

   Open `input_files/uni_sign/<platform>/input_uimage_secure` and change PRI_KEY and PUB_KEY to lnx.priv and lnx.pub respectively and run the following command. **`./uni_sign input_files/uni_sign/<platform>/input_uimage_secure`**

   Remember the "Key Hash" printed as it would be required in esbc_validate command in boot script. Say the hash of the key is <lnx_key_hash>

6. Create CSF header for rootfs

   ```
   ./gen_keys 1024 -p rootfs.priv -k rootfs.pub
   ```

   Open `input_files/uni_sign/<platform>/input_rootfs_secure` and change PRI_KEY and PUB_KEY to rootfs.priv and rootfs.pub respectively and run the following command.

   `./uni_sign input_files/uni_sign/<platform>/input_rootfs_secure`

   Remember the "Key Hash" printed as it would be required in esbc_validate command in boot script. Say the hash of the key is <rootfs_key_hash>

7. Create CSF Header for hardware device tree

   ```
   ./gen_keys 1024 -p dtb.priv -k dtb.pub
   ```

   Open `input_files/uni_sign/<platform>/input_dtb_secure` and change PRI_KEY and PUB_KEY to dtb.priv and dtb.pub respectively and run the following command. **`./uni_sign input_files/uni_sign/<platform>/input_dtb_secure`**

   Remember the "Key Hash" printed as it would be required in esbc_validate command in boot script. Say the hash of the key is <dtb_key_hash>

   Make sure that the fields in the input file input_rootfs_secure are same as mentioned in the address map

8. Write Boot script

   Bootscript is a U-Boot script image. Steps to create bootscript are given below :

   a. Create a text file bootscript.txt with following commands.

   ```
   esbc_validate <uImage CSF Header address>  <lnx_key_hash>
   esbc_validate <dtb CSF Header address>  <dtb_key_hash>
   esbc_validate <rootfs CSF Header address>  <rootfs_key_hahs>
   bootm <uImage Address> <rootfs address> <dtb address>
   ```

   NOTE

   Hashes would be the 256 bit string hash. These are the hashes of the key used to sign the respective images.

   b. Generate header over bootscript.txt which will be consumed by uboot command source

   tmp/sysroots/x86_64-linux/usr/bin/mkimage -A ppc -T script -a 0 -e 0x40 -d bootscript.txt bootscript

9. Generate CSF hdr for the boot script

   ```
   ./gen_keys 1024 -p bs.priv -k bs.pub
   ```

   Open `input_files/uni_sign/<platform>/input_dtb_secure` and change PRI_KEY and PUB_KEY to bs.priv and bs.pub respectively and run the following command.

   `./uni_sign input_files/uni_sign/<platform>/input_dtb_secure`

10.3.2.4.2.3 Running secure boot (Chain of Trust)

1. Setup the board for secure boot flow. You can choose any if the flows mentioned below.
   a. **Flow A**

      Program the ITS fuse.

      Or

   b. **Flow B**

      For protyping phase, don't blow the ITS fuse, instead set CFG_SB_DIS = 0. And put core in boot hold off mode.

   To put core in boot hold off mode :

   - P1010 : Set SW2.7 (CFG_BOOT_EN) = 1
   - BSC9132 : Set SW8.5 (CFG_BOOT_EN) = 0;
   - C293PCIE : Set SW7.1 (CFG_BOOT_EN) = 0

   To set CFG_SB_DIS = 0 on :

   - P1010 : Set SW2.1 (CFG_SB_DIS) = 0
   - BSC9131 : SW8.3 (CFG_SB_DIS) = 0 (for BSC9131QDS board)
   - BSC9132 : Set (CFG_SB_DIS) = 0 in DUTCFG12 (offset 0x06C) in FPGA image
   - C290 : Set SW7.6 (CFG_SB_DIS) = 0 (ON)

   For BSC9132 you can also program QIXIS registers from u-boot prompt using following i2c commands –

   i2c mw.l 0x66 0x6c 0xc7

   i2c mw.l 0x66 0x10 0x60

   i2c mw.l 0x66 0x10 0x30

   NOTE

   Don't power off the board if you want to retain the QIXIS settings

   In a manufacturing environment, it is recommended that all fuses be programmed at once, including the ITS and OEM Section Write Protect bits. In a prototyping environment, it may be preferable to leave ITS and Write Protect unprogrammed (relying on CFG_SB_DIS to initiate secure boot) until the developer has confidence in the secure boot process.

2. Blow other required fuses on the board (OTPMK, SRK hash and UID's).
   - OTPMK : It needs to be fused for both Flow A as well as Flow B.
   - SRK hash : It needs to be fused for Flow A but for Flow B it depends on choice either it can be fused or it can be written in shadow registers.
   - UID's: It needs to be fused for Flow A but for Flow B it depends on choice either it can be fused or it can be written in shadow registers.

   In case of Flow B, SRK hash and UID's can be written in shadow registers. As if, once fused it can't be changed.

   Note: SRK hash blown in the fuse should be same as the hash of the key pair being used to sign the ESBC u-boot. Step 2 of Signing the images using same key pair on page 2032

3. Flashing images:
   - In case of NOR, flash-

     CF header : 0x0.

     CSF Header : as specified in CF Header.

ESBC u-boot : as specified in CSF Header.

and all other images are flashed in NOR flash at location as described in the address map (Address map used for the demo on page 2064

- In case of NAND/SPI/SD/SDHC, flash-

  CF header : 0x0.

  CSF Header : as specified in CF Header.

  ESBC u-boot : as specified in CSF Header.

  and all other images are flashed in NOR flash only at location as described in the address map (Address map used for the demo on page 2064

  NOTE

  In case of NAND/SPI/SD/SDHC secure boot, next level image address to be validated is configured in ESBC u-boot as NOR flash address.

a. **Flow A** - All the images would have to be flashed at the current bank addresses. Once ITS fuse is blown, the control would automatically shift to ISBC on power on.

b. If you are using **Flow B**, you can use alternate bank for demo purpose. This would mean flashing the images on alternate bank addresses from Bank0 and then switching to Bank4.

4. Give a power on cycle to the board.

   a. For **Flow A** and **Flow B**

      - On power on, ISBC code would get control, validate the ESBC image.
      - ESBC image would further validate the signed linux, rootfs and dtb images
      - Linux would come up

   b. **Flow B**

      - Do switch settings according to the device (NAND/SPI/SD/SDHC).
      - Put the core in boot hold off mode.
      - On power on cycle, write SRKH, UIDs in the SFP shadow registers.
      - Bring the core out of boot hold off by writing to EEBPCR register.
      - On doing this, the secure boot flow as mentioned above would execute.

10.3.2.4.3 Chain of Trust with Confidentiality

This section presents the steps needed to be followed in order to execute Chain of Trust with confidentiality.

The demo would be divided into two parts:

1. Creating /encrypting images in form of blobs.
2. Decrypting the images, and booting from decrypted images.

Steps in the demo would be:

Step 1: Creating blobs

1. ISBC code would validate the ESBC code.
2. On successful validation, ESBC code would run, which would then validate the boot script.
3. On successful validation of boot script, commands in boot script would be executed.
4. The boot script contains commands to encapsulate next level images, i.e rootfs, linux uImage and device tree.

Step 2: Decrypting blob and booting

1. ISBC code would validate the ESBC code.
2. On successful validation, ESBC code would run, which would then validate the boot script.
3. On successful validation of boot script, commands in boot script would be executed.
4. The boot script contains commands to decapsulate/decrypt next level images, i.e rootfs, linux uImage and device tree.
5. After decryption, bootm command would be executed in boot script to pass control to Linux.

10.3.2.4.3.1 Other images required for the demo

Apart from SDK images described above, the following images are also required:

1. Encap Boot script
2. Decap Boot script
3. CF header for ESBC
4. CSF header for ESBC u-boot Image
5. CSF Header of the encap boot script
6. CSF Header of the decap boot script

The following section describes how to create the CSF headers and boot script.

10.3.2.4.3.2 Encap Bootscript

1. Create a bootscript_en.txt file with following commands:

```
blob enc <uImage address> 0x10000000 <uImage size> <key_modifier address>

erase <encapsulated uImage address> +<encapsulated uImage size>
cp.b 0x10000000 <encapsulated uImage address> <encapsulated uImage size>

blob enc <rootfs address> 0x20000000 <rootfs size> <key_modifier address>

erase <encapsulated rootfs address> +<encapsulated rootfs size>
cp.b 0x20000000 <encapsulated rootfs address>  <encapsulated rootfs size>

blob enc <dtb address> 0x1000000 <btb size> <key_modifier address>

erase <encapsulated dtb address> +<encapsulated dtb size>
cp.b 0x1000000 <encapsulated dtb address>  <encapsulated dtb size>
```

   For the addresses to load images refer Section Address map used for the demo on page 2064

2. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A ppc -T script -a 0 -e 0x40 -d bootscript_en.txt
bootscript_encap
```

10.3.2.4.3.3 Decap Bootscript

1. Create a bootscript_de.txt file with following commands:

```
blob dec <encapsulated uImage address> 0x10000000 <uImage size + 0x30> <key_modifier address>

blob dec <encapsulated rootfs address> 0x20000000 <rootfs size + 0x30>  <key_modifier address>

blob dec <encapsulated dtb address> 0x1000000 <dtb size + 0x30>  <key_modifier address>
```

```
bootm 0x10000000 0x20000000 0x1000000
```

For the addresses to load images refer Section Address map used for the demo on page 2064

The script decapsulates/decrypts the blob created by earlier boot script and boots using them.

NOTE

0x30(48 bytes) are added at the end of the encapsulated image which needs to be added while providing the size of image to be decapsulated in blob dec command.

2. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A ppc -T script -a 0 -e 0x40 -d bootscript_de.txt
bootscript_decap
```

10.3.2.4.3.4 Creating CSF Headers

- **CSF Header for ESBC**

  Use the command given below to generate the hdr for u-boot binary.

  ./uni_sign input_files/uni_sign/<platform>/<input file for uboot>

  Please change the binary name as per your uboot binary in “IMAGE_1”.

- **CSF Header for bootscript_encap and bootscript_decap**

  Use the command given below to generate the headers for bootscripts

  ./uni_sign input_files/uni_sign/<platform>/<input file for bootscript>

  Please change the binary name as per your bootscript in “IMAGE_1”.

10.3.2.4.3.5 Running secure boot (Chain of Trust with Confidentiality)

1. Setup the board for secure boot flow. You can choose any if the flows mentioned below.
   a. **Flow A**

      Program the ITS fuse.

      Or

   b. **Flow B**

      For protyping phase, don't blow the ITS fuse, instead set CFG_SB_DIS = 0 and put the core in boot hold off mode as described in Running secure boot (Chain of Trust) on page 2035 .

2. Blow other required fuses on the board (OTPMK, SRK hash and UID's).
   - OTPMK : It needs to be fused for both Flow A as well as Flow B.
   - SRK hash : It needs to be fused for Flow A but for Flow B it depends on choice either it can be fused or it can be written in shadow registers.
   - UID's: It needs to be fused for Flow A but for Flow B it depends on choice either it can be fused or it can be written in shadow registers.

   In case of Flow B, SRK hash and UID's can be written in shadow registers. As if, once fused it can't be changed.

   Note: SRK hash blown in the fuse should be same as the hash of the key pair being used to sign the ESBC u-boot. Step 2 of Signing the images using same key pair on page 2032

3. Flashing images:

- In case of NOR, flash-

  CF header : 0x0.

  CSF Header : as specified in CF Header.

  ESBC u-boot : as specified in CSF Header.

  and all other images are flashed in NOR flash at location as described in the address map (Address map used for the demo on page 2064

- In case of NAND/SPI/SD/SDHC, flash-

  CF header : 0x0.

  CSF Header : as specified in CF Header.

  ESBC u-boot : as specified in CSF Header.

  and all other images are flashed in NOR flash only at location as described in the address map (Address map used for the demo on page 2064

a. **Flow A** - All the images would have to be flashed at the current bank addresses. Once ITS fuse is blown, the control would automatically shift to ISBC on power on.

b. If you are using **Flow B**, you can use alternate bank for demo purpose. This would mean flashing the images on alternate bank addresses from Bank0 and then switching to Bank4.

4. Give a power on cycle to the board.

   a. For **Flow A** and **Flow B**

      - On power on, ISBC code would get control, validate the ESBC image.
      - ESBC image would further validate the bootscript.
      - Bootscript would encapsulate the Linux, rootfs and device tree and store the blobs at the desired locations.

   b. **Flow B**

      - Do switch settings according to the device (NAND/SPI/SD/SDHC).
      - Put the core in boot hold off mode.
      - On power on cycle, write SRKH, UIDs in the SFP shadow registers.
      - Bring the core out of boot hold off by writing to EEBPCR register.
      - On doing this, the secure boot flow as mentioned above would execute.

5. Replace the encap bootscript and its CSF header with decap bootscript and the CSF header of the decap bootscript respectively.

6. Give a power on cycle to the board.

   a. For **Flow A** and **Flow B**

      - On power on, ISBC code would get control, validate the ESBC image.
      - ESBC image would further validate the bootscript.
      - Bootscript would decapsulate the Linux, rootfs and device tree bloband store them on DDR
      - Bootm commnd in bootscript would execute on successful decapsulation
      - Linux prompt would come up. .

   b. **Flow B**

      - On power on cycle, u-boot prompt on bank 0 would come up.
      - On switching to alternate bank, the secure boot flow as mentioned above would execute.

10.3.2.5 Troubleshooting

Table 349. Troubleshooting

	Symptoms	Reasons and/or Recommended actions
1.	No print on UART console.	• Check the status register of sec mon block (location CCSRBAR + 0xe6014). Refer to the details of the register from the Reference Manual. Bits OTPMK_ZERO, OTMPK_SYNDROME and PE should be 0 otherwise there is some error in the OTPMK fuse blown by you. • If OTMPK fuse is correct (see Step 1), check the GUTS SBDCR (CCSRBAR + 0xe0f90) register for errors. Refer to Validation failures on page 2024 for error codes. • If **Error code = 0** then check the Security Monitor state in HPSR register of Sec Mon. **Sec Mon in Check State (0x9)** If ITS fuse = 1, then it means ISBC code has reset the board. This may be due to the following reasons: Hash of the public key used to sign the ESBC u-boot doesn't match with the value in SRK Hash Fuse Or Signature verification of the image failed **Sec Mon in Trusted State (0xd) or Non Secure State (0xb)** Check the entry point field in the ESBC header. It should be 0xcfffffffc for the demo described in Section 4. If entry point is correct, ensure that u-boot image has been signed with the correct input file.
2.	Instead of linux prompt, you get a u-boot command prompt .	You have not booted in secure boot mode. You never get a u-boot prompt in secure boot flow. Check Step 1 in Running secure boot (Chain of Trust) on page 2035. You would reach this stage if ITS = 0 and you are running normal uboot.
3	u-boot hangs or board resets	Some validation failure occurred in ESBC u-boot. Error code and description would be printed on u-boot console. Refer to Validation Failures from ESBC on page 2024 for more details on errors.

10.3.2.6 Trust Architecture and SFP Information

SoC	Trust Arch. Version	SFP Version	POVDD	DRVR		OTPMK	
				Algo (CST)	Register to check Hamming Error	Algo (CST)	Register to check Hamming Error

10.3.2.7 CF Header Data Structure Definition

The IBSC running on the core first authenticates the CF Header and then executes the configuration words.

P1010/ 9131/ 9132 Platforms

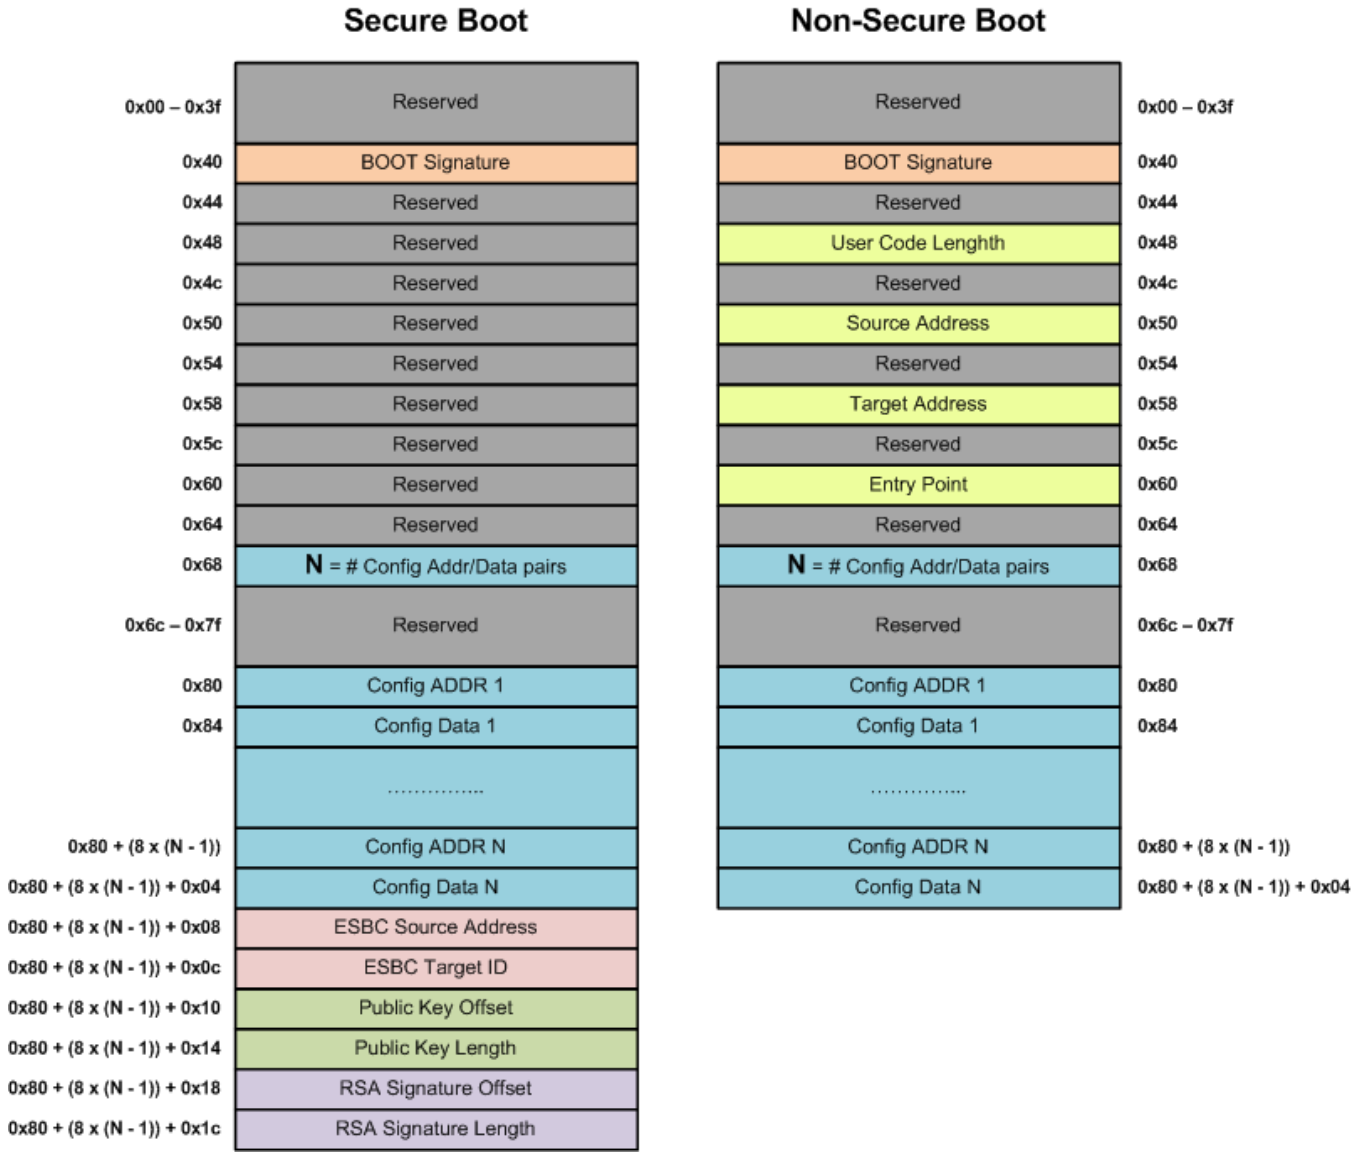

Figure 329. CF Header for P1010/ 9131/ 9132

Table 350. CF Header Format (P1010/ 9131/ 9132 Platforms)

Offset	Data Bits [0:31]
0x00-0x3F	**Reserved**
0x40-0x43	**BOOT signature**. This location should contain the value 0x424f_4f54, which is the ascii code for BOOT. The boot loader code searches for this signature. If the value in this location does not match the BOOT signature or the SD/MMC card does not contain a valid user code, the boot loader code disables the eSDHC and issues a hardware reset request of the SoC by setting RSTCR[HRESET_REQ].

Table continues on the next page...

Table 350. CF Header Format (P1010/ 9131/ 9132 Platforms) (continued)

Offset	Data Bits [0:31]
0x44-0x47	Reserved
0x48-0x4b	**User's code length**. Number of bytes in the user's code to be copied. This must be a multiple of the SD/MMC card's block size (and the user's code zero-padded if necessary to achieve that length). User's code length <= 2 GBytes. This is treated as reserved in Secure Boot Mode
0x4c-0x4f	Reserved
0x50-0x53	**Source Address**. Contains the starting address of the user's code as an offset from the SD/MMC card starting address. In Standard Capacity SD/MMC Cards, the 32-bit Source Address specifies the memory address in byte address format. This must be a multiple of the SD/MMC card's block size. In High Capacity SD Cards (>2 GBytes), the 32-bit Source Address specifies the memory address in block address format. Block length is fixed to 512 bytes as per the SD High Capacity specification . This is treated as reserved in Secure Boot Mode .
0x54-0x57	Reserved
0x58-0x5b	**Target Address**. Contains the target address in the system's local memory address space in which the user's code is copied to. This is a 32-bit effective address. The core is configured in such a way that the 36-bit real address is equal to this (with 4 most significant bits zero) . This is treated as reserved in Secure Boot Mode
0x5c-0x5f	Reserved
0x60-0x63	**Entry Point**. Contains the jump address in the system's local memory address space into the user's code first instruction to be executed. This is a 32-bit effective address. The core is configured in such a way that the 36-bit real address is equal to this (with 4 most significant bits zero). This is treated as reserved in Secure Boot Mode.
0x64-0x67	Reserved
0x68-0x6b	**N. Number of Configuration Address/Data pairs**. Must be 1<=N<=44 if running in secure mode. Must be 1<=N<=48 if running in legacy mode. (but is recommended to be as small as possible).

0xb10-0xe10	Key 4 value. (Remaining bytes will be padded with zero)

10.3.2.8 CSF Header Data Structure Definition

The CSF Header provides the ISBC with most of the information needed to validate the image.

P1010/ 9131/ 9132 Platforms

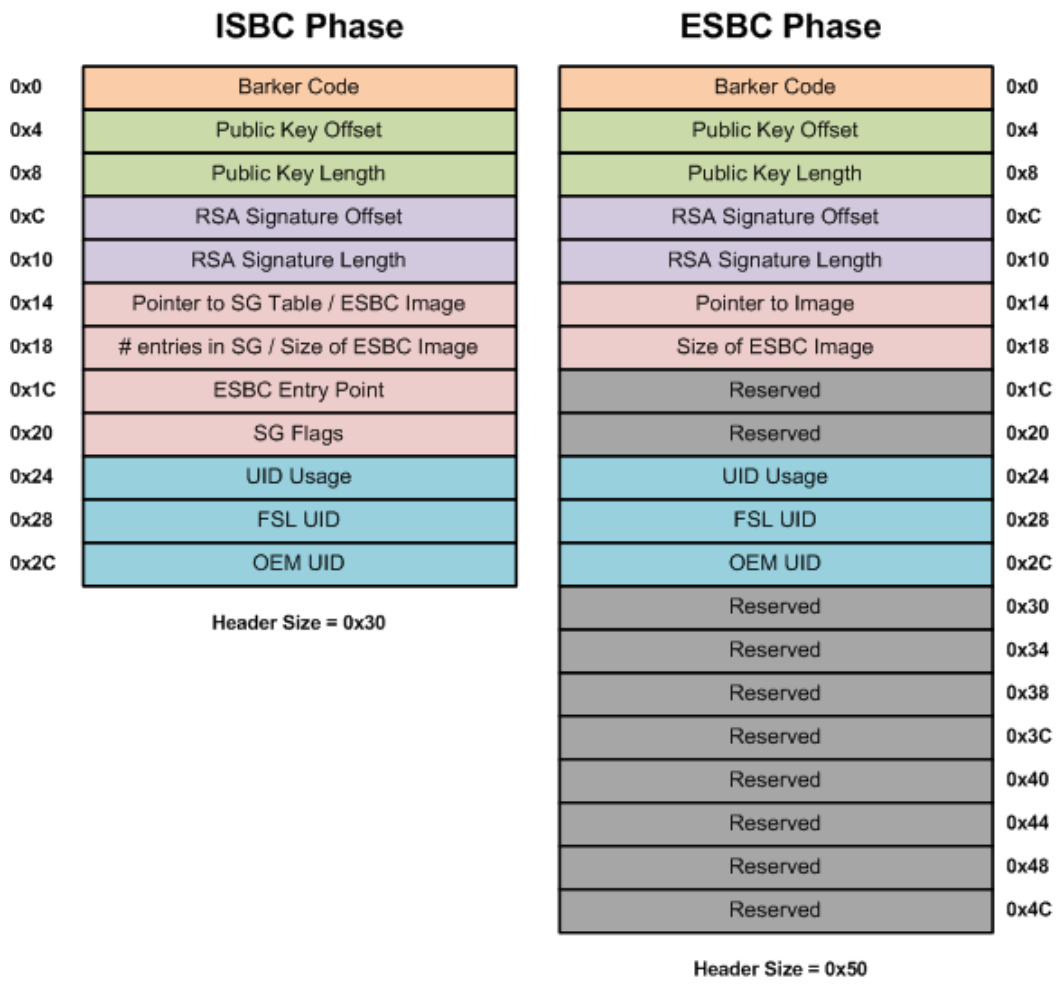

Figure 331. CSF Header for P1010/ 9131/ 9132 (ISBC and ESBC Phase)

Table 356. CSF Header Format (P1010/ 9131/ 9132 Platforms)

Offset	Data Bits [0:31]
0x00-0x03	**Barker code**. This location should contain the value: 0x68392781. The ISBC code searches for this Barker code. If the value in this location does not match the Barker code, the ISBC stops execution and reports error.
0x04-0x07	**Public key offset**. This location contains an offset in bytes of the public key from the start of CSF header. Using this offset and the public key length, the public key is read.
0x08-0x0b	**Public key length in bytes**. (Value populated here should be twice of Modulus size). Supported sizes are 256, 512 or 1024 bytes (2 * 1024, 2 * 2048 , 2 * 4096 bits).

Table continues on the next page...

Table 356. CSF Header Format (P1010/ 9131/ 9132 Platforms) (continued)

Offset	Data Bits [0:31]
0x0c-0x0f	**RSA Signature offset**. This location contains an offset(in bytes) of the RSA signature from the start of CSF header. Using this offset and the Signature length, the RSA signature is read. The RSA signature is calculated over CSF Header, Scatter Gather table and ESBC images.
0x10-0x13	**RSA Signature length in bytes**.
0x14-0x17	**For ISBC Phase**: Based on the Scatter Gather flag in CSF header, this location can either be treated as **Pointer to Scatter Gather table or the address of ESBC image**. **For ESBC Phase**: This location is treated as **address of image**(linux/bootscript/rootfs/dtb) to be validated.
0x18-0x1b	**For ISBC Phase**: Based on the Scatter gather flag in CSF Header, this location can either be treated as **number of entries in SG table or ESBC image size** in bytes. **For ESBC Phase**: Size of image to be validated.
0x1c-0x1f	**For ISBC Phase**: **ESBC entry point**. ISBC transfers control to this location upon successful validation of ESBC image(s). **For ESBC Phase**: Reserved.
0x20-0x23	**Reserved** .(Earlier this field was SG Flag. SG flag is always assumed to be 1)
0x24-0x27	**Unique ID Usage**. UIDs present in the CSF Header are compared to the corresponding UIDs in the SFP, and are included in the ESBC validation. 0x0000 - No UIDs are present in CSF header 0x0001 - FSL_UID and OEM_UID are present in CSF header 0x0002 - Only OEM_UID present in CSF header 0x0004 - Only FSL_UID present in CSF header
0x28-0x2b	**NXP unique ID**. A unique 32 bit value, which is specific to NXP. This value is compared with the FSL ID in Secure Fuse Processor 's FSL-ID registers

Table continues on the next page...

Table 360. CSF Header Format (C290 Platform)

Offset	Data Bits [0:31]
0x00-0x03	**Barker code**. This location should contain the value: 0x68392781. The ISBC code searches for this Barker code. If the value in this location does not match the Barker code, the ISBC stops execution and reports error.
0x04-0x07	If the srk_table_flag is not set : • **Public key offset**: This location contains an address which is the offset of the public key from the start of CSF header. Using this offset and the public key length, the public key is read. If srk_table_flag is set: • **Srk table offset**: This location contains an address which is the offset of the srk table from the start of CSF header. Using this offset and the number of entries is SRK Table, the SRK table is read.

Table continues on the next page...

Table 360. CSF Header Format (C290 Platform) (continued)

Offset	Data Bits [0:31]
0x08	**Srk table flag**. This flag indicates whether hash burnt in srk fuse is of a single key or of srk table.
0x09-0x0b	If the srk_table_flag is not set : • **Public key length**: This location contains the length of the public key in bytes. If srk_table_flag is set: • 0x09 – **Key Number** from srk table which is to be used for verification. • 0x0a-0x0b – **Number of entries** in srk table. Minimum number of entries in table = 1, Maximum = 4.
0x0c-0x0f	**RSA Signature offset**. This location contains an offset(in bytes) of the RSA signature from the start of CSF header. Using this offset and the Signature length, the RSA signature is read. The RSA signature is calculated over CSF Header, Scatter Gather table and ESBC images.
0x10-0x13	**RSA Signature length in bytes**.
0x14-0x17	**For ISBC Phase**: **SG Table offset** This location contains an address which is the offset of the SG table from the start of CSF header. Using this offset and the number of entries is SG Table, the SG table is read. **For ESBC Phase**: **Address of the image to be validated**.
0x18-0x1b	**For ISBC Phase**: **Number of entries in SG Table** (Earlier ,Based on the Scatter gather flag in CSF Header, this location can either be treated as number of entries in SG table or ESBC image size in bytes.). **For ESBC Phase**: **Size of image** to be validated
0x1c-0x1f	**For ISBC Phase**: **ESBC entry point**. ISBC transfers control to this location upon successful validation of ESBC image(s). **For ESBC Phase**: Reserved
0x20-0x23	**Reserved** .(Earlier this field was SG Flag. SG flag is always assumed to be 1 in unified implementation.)
0x24	For ISBC Phase: Reserved For ESBC Phase: Reserved

Table continues on the next page...

Table 360. CSF Header Format (C290 Platform) (continued)

Offset	Data Bits [0:31]
0x25	**For ISBC Phase**: **Secondary Image flag** Indicates if user has a secondary image available in case of failures in validating primary iamge.Valid in case of primary Images's Header. **For ESBC Phase**: Reserved
0x26-0x27	**Unique ID Usage**. UIDs present in the CSF Header are compared to the corresponding UIDs in the SFP, and are included in the ESBC validation. 0x00 - No UIDs are present in CSF header 0x01 - FSL_UID and OEM_UID are present in CSF header 0x02 - Only OEM_UID present in CSF header 0x04 - Only FSL_UID present in CSF header
0x28-0x2b	**NXP unique ID**. A unique 32 bit value, which is specific to NXP. This value is compared with the FSL ID in Secure Fuse Processor 's FSL-ID registers
0x2c-0x2f	**OEM unique ID**. A unique 32 bit value, which is specific to OEM. This value is compared with the OEM ID in Secure Fuse Processor 's OEM-ID registers
0x30-0x33	**For ISBC Phase**: **Housekeeping area address** This is address of start of a memory which can be accessed by devices on SOC bus. (DDR, L3 cache configured as SRAM). The area should have been pre-configured by user through PBL commands or configuration header. **For ESBC Phase**: Reserved
0x34-0x37	**For ISBC Phase**: **Size of the housekeeping area** Size of the pre-configured memory which can be used by Boot Rom Code. **For ESBC Phase**: Reserved.
0x38-0x3f	Reserved
0x40-0x4f	For ISBC Phase: Not Applicable For ESBC Phase: Reserved

Table 362. Signature (C290 Platform)

Offset	Data Bits [0:31]
0x00-size	The RSA signature calculated over CSF Header, Scatter Gather table and ESBC image(s).

Table 363. Public key (C290 Platform)

Offset	Data Bits [0:31]
0x00-size	Public Key Value. The hash of this public key is compared with the hash stored in Secure Fuse Processor SRKH registers.

Table 364. SRK Table (C290 Platform)

Offset	Data Bits [0:31]
0x00-0x03	Key 1 length
0x04-0x403	Key 1 value. (Remaining bytes will be padded with zero)
0x404-0x407	Key 2 length
0x408-0x807	Key 2 value. (Remaining bytes will be padded with zero)
0x808-0x80b	Key 3 length
0x80c-0xb0b	Key 3 value. (Remaining bytes will be padded with zero)
0xb0c-0xb0f	Key 4 length
0xb10-0xe10	Key 4 value. (Remaining bytes will be padded with zero)

10.3.2.9 ISBC Validation Error Codes

There are many reasons the IBR could fail to validate the ESBC. Technicians with debug access can check the GUTS Internal BootROM Error Code Register (IBRECR: CCSRBAR + 0xe0f90) register to obtain an error code

P1010/ 9131/ 9132 platforms

Table 365. ISBC Validation Failures (P1010/ 9131/ 9132 platforms)

Value	Code	Definition
0x1	ERROR_CRITICAL	Error due to critical exceptions
0x2	ERROR_BAD_ADDRESS	IBR accessed any unmapped address.
0x3	ERROR_MISC	Miscellaneous Exception
0x100	ERROR_CORE_NON_ZERO	Core is not boot core i.e core0
0x101	ERROR_STATE_NOT_CHECK	SNVS not in CHECK state
0x102	ERROR2_STATE_NOT_CHECK	SEC_MON State Machine not in CHECK state, when trying to transition it to Trusted/Non Secure/Soft Fail state

Table continues on the next page...

Table 365. ISBC Validation Failures (P1010/ 9131/ 9132 platforms) (continued)

Value	Code	Definition
0x103	ERROR_TARGET_NOT_SUPPORTED_IN_NON_SECURE	The target is not supported in legacy mode
0x201	ERROR_BOOT_SIG_MISMATCH	Boot signature mismatch in CF header
0x202	ERROR_CF_HASH_COMPARE_EM	CF header signature failure
0x204	ERROR_CF_HEADER_KEY_LEN	Wrong key length in CF header
0x205	ERROR_CF_HEADER_SIG_LEN	Wrong signature length in CF header
0x206	ERROR_CF_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Key length not twice of signature length
0x207	ERROR_CF_HEADER_USER_CODE_LEN	Wrong user code length in CF header
0x208	ERROR_CF_HEADER_CMDS_EXCED_LIMIT	More than allowed configuration commands in CF header
0x209	ERROR_ESBCHDRLOC_NOT_ALIGNED	ESBC header address not aligned to 512 byte boundary in case of SD/MMC
0x20a	ERROR_CF_HASH_COMPARE_KEY	Key hash failure in CF header
0x301	ERROR_ESBC_HDR_LOC	ESBC header not within 3.5G boundary
0x302	ERROR_ESBC_HEADER_BARKER	Barker code error in ESBC header
0x303	ERROR_ESBC_HEADER_KEY_LEN	Wrong key length in ESBC header
0x304	ERROR_ESBC_HEADER_SIG_LEN	Wrong signature length in ESBC header
0x305	ERROR_ESBC_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Key length not twice of signature length in ESBC header
0x306	ERROR_ESBC_HEADER_SG_TABLE_ADDR_NULL	SG table address is NULL
0x307	ERROR_ESBC_HEADER_SG_TABLE_ADDR_NOT_IN_3_5G	SG table address not within 3.5G boundary
0x308	ERROR_ESBC_HEADER_KEY_MOD_1	Public key Modulus most significant bit not set
0x309	ERROR_ESBC_HEADER_KEY_MOD_2	Public key Modulus in header not odd
0x30a	ERROR_ESBC_HEADER_SIG_KEY_MOD	Signature not less than modulus

Table continues on the next page...

Table 365. ISBC Validation Failures (P1010/ 9131/ 9132 platforms) (continued)

Value	Code	Definition
0x30b	ERROR_ESBC_HEADER_SG_ENTRIES_NULL	SG entries address is NULL
0x30c	ERROR_ESBC_HEADER_SG_ENTRIES_NOT_IN_3_5G	SG entries not within 3.5G boundary
0x30d	ERROR_ESBC_HEADER_SG_ESBC_EP	ESBC entry point not within one of the SG entries
0x30e	ERROR_HASH_COMPARE_KEY	Key hash failure in ESBC header
0x30f	ERROR_HASH_COMPARE_EM	Signature failure in ESBC header
0x310	ERROR_SSM_CHECKSTS	SNVS not in CHECK state
0x311	ERROR_SSM_TRUSTSTS	SNVS not in TRUSTED state
0x312	ERROR_FSL_UID	FSL UIDs present in ESBC header and SFP don't match
0x313	ERROR_OEM_UID	OEM UIDs present in ESBC header and SFP don't match
0x315	ERROR_SGL_ENTIRES_NOT_SUPPORTED	Number of entries in SG table exceeds maximum limit i.e 8
0x316	ERROR_SG_ENTRY_NOT_ALIGNED	SG entries address not aligned in case of SD/MMC
0x317	ESBCHDR_PKEY_NOT_ALIGNED	Key offset not aligned in case of SD/MMC
0x318	ESBCHDR_SIGN_NOT_ALIGNED	Signature offset not aligned in case of SD/MMC
0x401	ERROR_NAND_READ_TIMEOUT	Timeout while reading from NAND device.
0x403	ERROR_NAND_FTOER	FTOER error in NAND EVTER during Boot Done
0x404	ERROR_NAND_ECCER	ECCER error in NAND EVTER during Boot Done
0x405	ERROR_NAND_BBT_FULL	Bad Block Table is full
0x500	ERROR_ESDHC_CARD_DETECT_FAIL	No card present or card not inserted properly in the sdhc slot
0x501	ERROR_ESDHC_UNUSABLE_CARD	The card is not in usable state
0x502	ERROR_ESDHC_COMMUNICATION_ERROR	Communication Error
0x503	ERROR_ESDHC_READ_UNALIGNED	The offset being read is not aligned with the block size
0x600	ERROR_ESPI_READID	The Flash ID is invalid.
0x601	ERROR_ESPI_BOOT_SIGN	Unable to read Boot SIGN in both 24 bit and 16 bit mode.

Table continues on the next page...

Table 365. ISBC Validation Failures (P1010/ 9131/ 9132 platforms) (continued)

Value	Code	Definition
0x602	ERROR_ESPI_READ_TIMEOUT	Timeout while reading data from SPI.

C29x platforms

When the device is booted with the assistance of code from the Internal Boot ROM, including normal boot from SPI or SD and secure boot from any interface, the errors are logged in the GUTS registers IBRECR1 or IBRECR2. These can be read via debugger to determine the reason for failure.

Errors in the system can be of following types:

1. Core Exceptions
2. System State Failures
3. Header Checking Failures
   a. CF Header Checking Failures
   b. General CSF (ESBC) Header Checking Failures
   c. Key/Signature/UID related errors
4. Verification Failures
5. Driver errors
6. SEC errors

Internal BootROM Error Code Register 1 (IBRECR1)	CCSRBAR + 0xe0f90 Error code for validation of primary image and all core exceptions, system state failures and CF Header checking failures.
Internal BootROM Error Code Register 2 (IBRECR2)	CCSRBAR + 0xe0f94 Error code for validation of secondary image. Core Exceptions, System State Failures and CF Header Checking Failures cannot occur during verification of the secondary/ alternate image, and are not observed in this register.

Table 366. Core Exceptions (C29x platform)

Value	Code	Definition
0x1	ERROR_MACHINECHECK	Machine check Exception
0x2	ERROR_DSI	DSI Exception
0x3	ERROR_ISI	ISI Exception
0x4	ERROR_CRITICAL	Critical Exception
0x5	ERROR_ALIGN	Alignment Exception
0x6	ERROR_PROG	Program Exception
0x13	ERROR_DATA_TLB	Data TLB Miss

Table continues on the next page...

Table 366. Core Exceptions (C29x platform) (continued)

Value	Code	Definition
0x14	ERROR_INST_TLB	Instruction TLb Miss
0x20	ERROR_MISC	Any other exception

Table 367. System State Failures (C29x platform)

Value	Code	Definition
0x100	ERROR_CORE_NON_ZERO	ISBC is not running on CPU0
0x101	ERROR_STATE_NOT_CHECK	SEC_MON State Machine not in CHECK state at start of ISBC. Some Security violation could have occurred.
0x102	ERROR2_STATE_NOT_CHECK	SEC_MON State Machine not in CHECK state, when trying to transition it to Trusted/Non Secure/Soft Fail state
0x103	ERROR_SSM_TRUSTSTS	SEC_MON State Machine not in TRUSTED state at end of ISBC.

Table 368. CF Header Checking Failures for Non Secure Boot (C29x platforms)

Value	Code	Definition
0x201	ERROR_BOOT_SIG_MISMATCH	Boot signature mismatch in CF header
0x208	ERROR_CF_HEADER_CMDS_EXCEED_LIMIT	More than allowed configuration commands in CF header

Table 369. CF Header Checking Failures for Secure Boot (C29x platforms)

Value	Code	Definition
0x201	ERROR_BOOT_SIG_MISMATCH	Boot signature mismatch in CF header
0x202	ERROR_CF_HASH_COMPARE_EM	CF header signature failure
0x204	ERROR_CF_HEADER_KEY_LEN	Wrong key length in CF header
0x205	ERROR_CF_HEADER_SIG_LEN	Wrong signature length in CF header
0x206	ERROR_CF_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Key length not twice of signature length
0x207	ERROR_CF_HEADER_USER_CODE_LEN	Wrong user code length in CF header
0x208	ERROR_CF_HEADER_CMDS_EXCEED_LIMIT	More than allowed configuration commands in CF header
0x20a	ERROR_CF_HASH_COMPARE	Key hash failure in CF header

Table continues on the next page...

Table 369. CF Header Checking Failures for Secure Boot (C29x platforms) (continued)

Value	Code	Definition
0x20b	ERROR_CF_INVALID_SRK_TBL	Number of entries field in CSF Header is 0 or greater than 4(This is when srk_flag in header is 1)
0x20c	ERROR_CF_INVALID_KEY_NUM	Key number to be used from srk table is not present in table. (This is when srk_flag in header is 1)
0x20d	ERROR_CF_KEY_REVOKED	Key selected from srk table has been revoked(This is when srk_flag in header is 1)
0x20e	ERROR_CF_INVALID_SRK_ENTRY_KEYLEN	Key length specified in one of the entries in srk table is not one of the supported values (This is when srk_flag in header is 1)

Table 370. General CSF (ESBC) Header Checking Failures (C29x platforms)

Value	Code	Definition
0x301	ERROR_ESBC_HDR_LOC	ESBC header location is not in 3.5G space
0x302	ERROR_ESBC_HEADER_BARKER	Barker code in the header is incorrect.
0x303	ERROR_ESBC_HEADER_SG_ENTRIES_NOT_IN_3_5G	SG table/ESBC image address (header address + image offset in sg table) is beyond 3.5G
0x304	ERROR_ESBC_HEADER_SG_ESBC_EP	ESBC entry point in header not within ESBC address range
0x305	ERROR_SGL_ENTIRES_NOT_SUPPORTED	Number of entries in SG table exceeds maximum limit i.e 8
0x306	ERROR_ESBC_HEADER_HKAREA_LEN_ZERO	Houskeeping area not provided in header
0x307	ERROR_ESBC_HEADER_HKAREA_NOT_IN_3_5G	House keeping area not in 3.5G boundary
0x308	ERROR_ESBC_HEADER_HKAREA_LEN_INSUFFICIENT	Housekeeping area length provided is not sufficient.
0x309	ERROR_SG_TABLE_NOT_IN_3_5	SG Table is not in 3.5G boundary
0x310	ERROR_ESBC_HEADER_HKAREA_NOT_4K_ALIGNED	House keeping area is not aligned to 4K boundary
0x311	ERROR_SGL_ENTRIES_SIZE_ZERO	SG table has entry with size zero.

Table 371. Key/Signature/UID related errors (C29x platforms)

Value	Code	Definition
0x320	ERROR_ESBC_HEADER_KEY_LEN	Length of public key in header is not one of the supported values.
0x321	ERROR_ESBC_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Public key is not twice the length of the RSA signature

Table continues on the next page...

Table 371. Key/Signature/UID related errors (C29x platforms) (continued)

Value	Code	Definition
0x322	ERROR_ESBC_HEADER_KEY_MOD_1	Most significant bit of modulus in header is zero.
0x323	ERROR_ESBC_HEADER_KEY_MOD_2	Modulus in header is even number
0x324	ERROR_ESBC_HEADER_SIG_KEY_MOD	Signature value is greater than modulus in header
0x325	ERROR_FSL_UID	FSL_UID in ESBC Header did not match the FSL_UID in SFP if fsl uid flag Is 1
0x326	ERROR_OEM_UID	OEM_UID in ESBC Header did not match the OEM_UID in SFP if oem uid flag is 1.
0x327	ERROR_INVALID_SRK_NUM_ENTRY	Number of entries field in CSF Header is > 4(This is when srk_flag in header is 1)
0x328	ERROR_INVALID_KEY_NUM	Key number to be used from srk table is not present in table. (This is when srk_flag in header is 1)
0x329	ERROR_KEY_REVOKED	Key selected from srk table has been revoked(This is when srk_flag in header is 1)
0x32a	ERROR_INVALID_SRK_ENTRY_KEYLEN	Key length specified in one of the entries in srk table is not one of the supported values (This is when srk_flag in header is 1)
0x32b	ERROR_SRK_TBL_NOT_IN_3_5	SRK Table is not in 3.5G boundary (This is when srk_flag in header is 1)
0x32c	ERROR_KEY_NOT_IN_3_5G	Key is not in 3.5G boundary

Table 372. Verification Failures (C29x platforms)

Value	Code	Definition
0x340	ERROR_HASH_COMPARE_KEY	Super Root Key Hash Comparison failure. Mismatch in the hash of the public key/srk table as present in the header with the value in the SRK HASH fuse.
0x341	ERROR_HASH_COMPARE_EM	RSA signature check failure. Signature provided by you in the header doesn't match with the signature of the ESBC image generated by ISBC. The ESBC image loaded by you may be different than the image used while generating the signature(using CST)

Table 373. Driver errors (C29x platforms)

Value	Code	Definition
0x401	ERROR_NAND_READ_TIMEOUT	Timeout while reading from NAND device.
0x403	ERROR_NAND_FTOER	FTOER error in NAND EVTER during Boot Done

Table continues on the next page...

Table 373. Driver errors (C29x platforms) (continued)

Value	Code	Definition
0x404	ERROR_NAND_ECCER	ECCER error in NAND EVTER during Boot Done
0x405	ERROR_NAND_BBT_FULL	Bad Block Table is full
0x500	ERROR_ESDHC_CARD_DETECT_FAIL	eSDHC is unable to detect any SD/SDHC/MMC card.
0x501	ERROR_ESDHC_UNUSABLE_CARD	There is no response from the card on sending the command to get OCR value or the controller is unable to determine the card type.
0x502	ERROR_ESDHC_COMMUNICATION_ERROR	Error in setting the block size or reading a block.
0x503	ERROR_ESDHC_READ_UNALIGNED	The offset being read is not aligned with the block size.
0x600	ERROR_ESPI_READID	The Flash ID is invalid.
0x601	ERROR_ESPI_BOOT_SIGN	Unable to read Boot SIGN in both 24 bit and 16 bit mode.
0x602	ERROR_ESPI_READ_TIMEOUT	Timeout while reading data from SPI.

Table 374. SEC Failures (C29x platforms)

Value	Code	Definition
0x700	ERROR_SEC_ENQ	Error when enqueuing to SEC
0x701	ERROR_SEC_DEQ	Sec Block returned some error when dequeuing from it.
0x702	ERROR_SEC_DEQ_TO	Timeout when trying to deq from SEC
0x1	ERR_SELF_TEST_FAILED	Self Test executed on RNG returned Failure
0x10000	ERR_RNG_INSTANTIATE_FAILED	RNG Instantiation failed.

10.3.2.10 Address map used for the demo

The addresses below are effective addresses as mapped by u-boot.

P1010/ 9131/ 9132 /C290 platforms

Table 375. Memory map for P1010/ 9131/ 9132 /C290 platforms

NOTE

While running for chain of trust with confidentiality:

- **P1010**: Flash (DTB, uImage, rootfs) at above specified locations and then replace them with (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)).
- **BSC9131**: Flash (DTB, uImage, rootfs) at above specified locations and then replace them with (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)).
- **BSC9132**: There are two choices either Flash (DTB, uImage, rootfs) at above specified locations and then replace them with (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)) or Flash (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)) at location within **8B000000 - 8FF5FFFF** as this location is free for use.
- **C290**: There are two choices either Flash (DTB, uImage, rootfs) at above specified locations and then replace them with (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)) or Flash (DTB(encapsulated), uImage(encapsulated), rootfs(encapsulated)) at location within **EE700000 - EFF5FFFF** as this location is free for use.
- To use 512KB u-boot change, address from eff40000 to eff80000

10.3.3 Service Processor (SP) Based Platforms

10.3.3.1 Secure Boot Introduction

There are three steps in the boot flow:

1. Service Processor Boot ROM

   SP provides pre-boot initialization and secure boot capabilities. The on-chip SP Boot ROM offers read-only, non-volatile storage for the Boot ROM code, including the internal secure boot code (ISBC) sub-routine for image validation. This Boot ROM is an integral part in the booting of the SOC in non-secure and secure boot modes.

2. GPP Boot ROM

   The on-chip GPP Boot ROM executes when the GPP cores are released from reset and is reponsible for passing control to next step in the boot flow i.e. the boot-loader validated by the SP.

3. Boot Loader

   The Boot Loader might further contain the External Secure Boot Code (ESBC) sub-routine for validation of next level images.

This document is intended for end-users to demonstrate the image validation process which happens in ISBC and ESBC.

The image validation can be split into stages, where each stage performs a specific function and validates the subsequent stage before passing control to that stage.

The Root of Trust is already established in the ISBC code residing in the Boot ROM which validates the Boot Loader 1.

Boot Loader 1 performs minimal SoC configuration before validating the Next Executable(s) which is/are known as ESBC image(s).

The flow includes validation of all ESBC images by a previously validated image before its execution to form a **Chain of TRUST**. The reference ESBC code also contains the functionality to form a **Chain of TRUST with confidentiality** where the next level images are kept on flash after encryption.

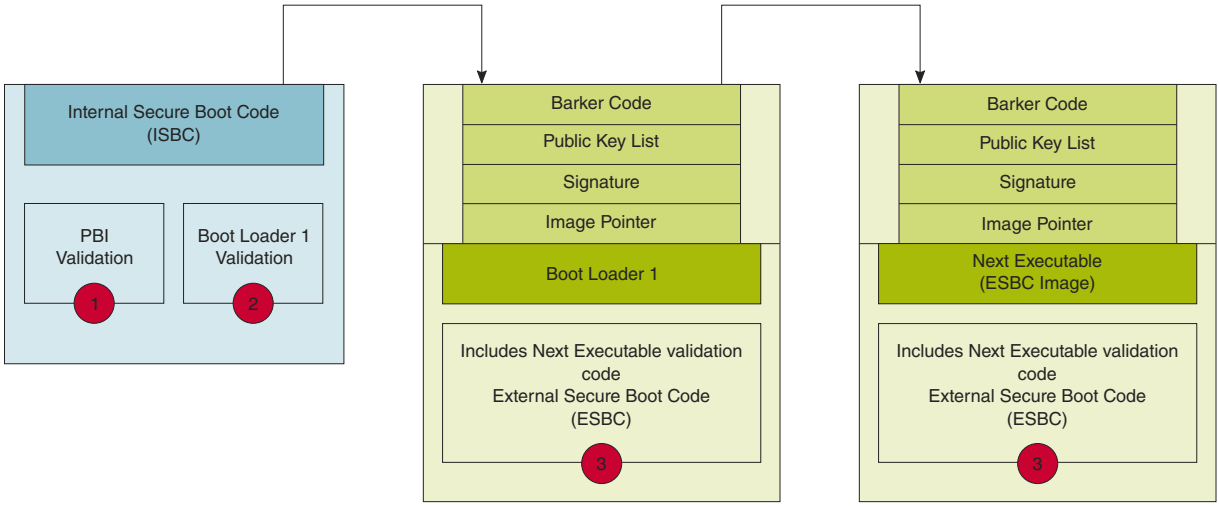

Figure 333. Chain of Trust

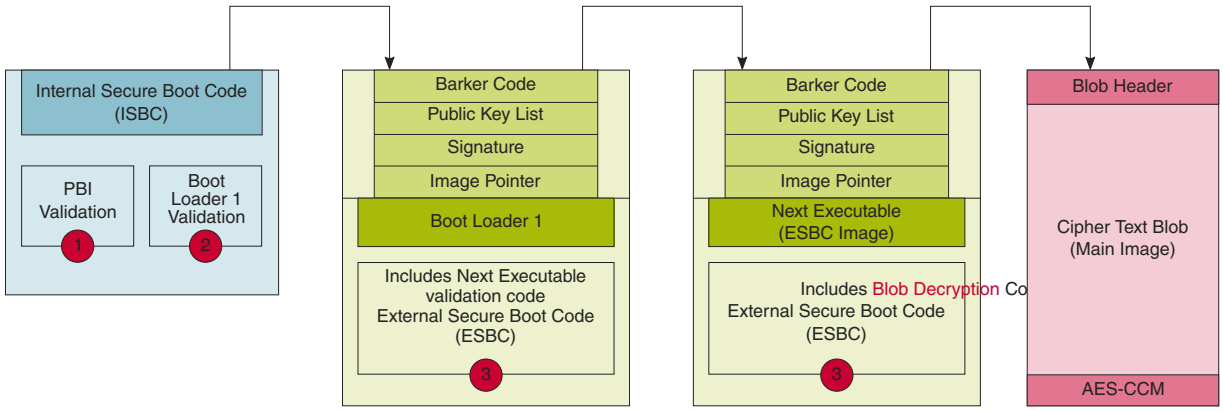

Figure 334. Chain of Trust with confidentiality

The validated ESBC image is allowed to use the One Time Programmable Master Key to decrypt system secrets. Cryptographic blob mechanism is used to establish Chain of trust with confidentiality.

The above is explained in detail in coming sections.

As depicted in figure(s) above, there are three types of images which need to be validated as part of Secure Boot.

1. PBI image by ISBC
2. Boot Loader 1 image by ISBC
3. Next level image(s) by ESBC

Typically ESBC images would include:

Boot Loader 2 - n	In case Boot Loader is split in to multiple stages (Typical example is in case of NAND, SD Boot in which there is a mini-boot loader loaded on OCRAM which is Boot Loader stage 1 verified by ISBC. Boot Loader 2 is loaded on DDR, which must be validated by the Boot Loader 1.
MC/AIOP images	Management Complex images
LINUX	The operating system to be executed on the SoC.

10.3.3.1.1 Secure Boot process

Secure boot process uses a digital signature validation routine already present in ISBC residing in SP Boot ROM. This routine performs validation using HW bound RSA public key to decrypt the signed hash and compare it to a freshly calculated hash over the same system image. If the comparison passes, the image can be considered as authentic.

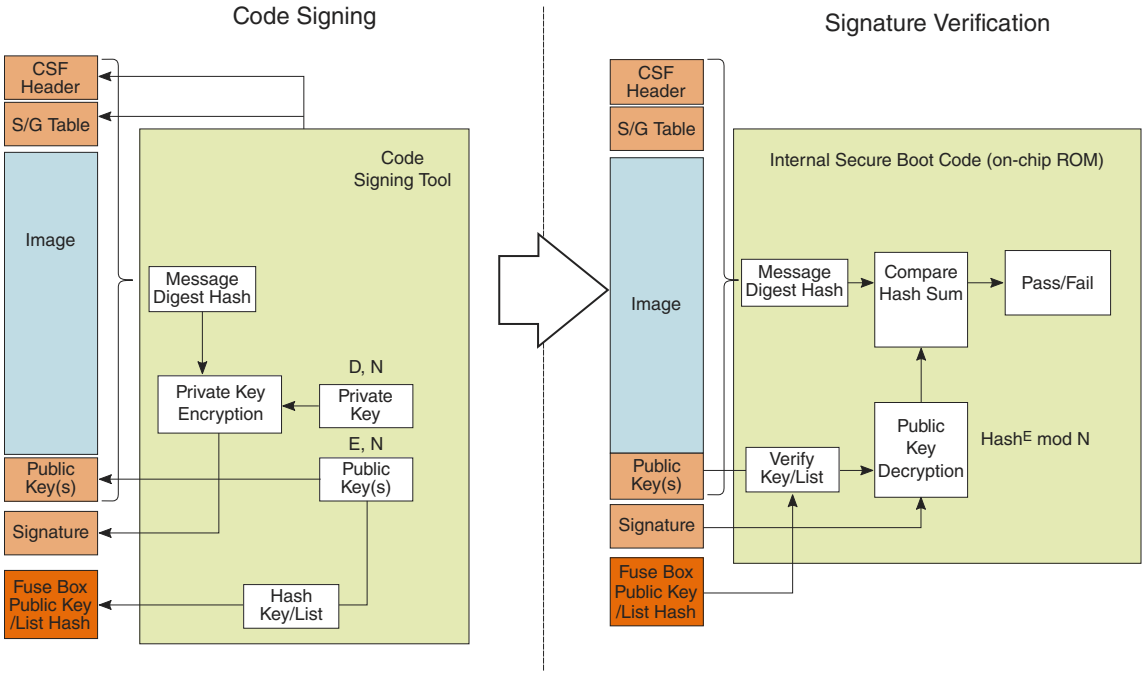

Figure 335. Secure Boot Process

As shown in the left side of the figure, the Code Signing Tool adds the following:

CSF Header	Command Sequence File Header This header provides the ISBC with flags, pointers, offsets, and lengths necessary to perform image validation.
S/G Table	Scatter Gather Table Optional (N/A for some stages which support only single image) Allows support for multiple non-contiguous images.
Public Key list	SRK (Super Root Key) Table One or more public keys is appended to the image. The CSF header indicates which of the keys is to be used in signature validation.
Signature	The SHA-256 hash of the CSF header + S/G table + Image + Public Key(s), encrypted with a RSA private key corresponding to one of the public keys in the key list.

As part of the code signing process, the CST also supports:

Generating RSA public and private key pairs	The RSA private key is exported for the OEM to store securely The CST also supports using public & private keys input by the OEM
Hashing the public key or public key list	This hash becomes the Super Root Key Hash which is stored in the SFP

At a high level, the secure boot process runs code signing in reverse.

1. The ISBC locates the CSF header and S/G table to further locate the image, public key list, and signature
2. The public key (list) is hashed and compared to the SRKH
3. If the public key is good, it is used to decrypt the signature (recover the hash)
4. The CSF header + S/G table + Image + Public key list are hashed, with the result compared to above. If the two hashes match, image is considered to be authentic.

10.3.3.1.1.1 Super Root Key (SRK)

These are RSA public and private key pairs. Private keys are used to sign the images and public keys are used to validate the image during ISBC and ESBC phase.

Public keys are embedded in the header and the hash of SRK table is fused in SRKH register of SFP.

These are Hardware Bound Keys, once the hash is fused the public private key pair can not be modified.

Keys of sizes 1k, 2k and 4k are supported in NXP Secure Boot Process.

It is the OEM's responsibility to tightly control access to the RSA private signature key. If this key is ever exposed, attackers will be able to generate alternate images that will pass secure boot.

If this key is ever lost, the OEM will be unable to update the image.

Key Revokation	Trust Architecture provides support for revoking the RSA public keys used by the ISBC to verify the ESBC. The RSA public keys used for this purpose are called super root keys. The SRK table supports maximum of 8 public keys and user has the option to revoke up to 7 keys. During secure boot, the ISBC checks the key number indicated in the CSF header against the revocation fuses in the SFP's OEM Security Policy Register (SFP_OSPR). If the key is revoked, the image validation fails.

10.3.3.2 ISBC Phase

At reset, Service Processor core is released and begins executing instructions from reset vector address 0x0 which is mapped to Internal Boot ROM. The Internal Boot ROM contains the code known as Internal Secure Boot Code (ISBC). The main steps in ISBC flow are defined below.

10.3.3.2.1 ISBC for PBI validation

1. **Sec_Mon check**: Confirms that the Sec_Mon is in the Check state. If not, it writes a 'fail' bit in a Sec_Mon control register, leading to a state transition.
2. **PBI command check**: Verify that the first PBI command is 'LOAD SEC HDR'. If not found, an error is raised.
3. **Valid header check**: Check for a valid preamble and correct B0/1 flag set as 0 in the header. If not, an error is raised.
4. **CSF parsing and public key check**; If ISBC finds a valid CSF header, it parses the CSF header to locate the public key from SRK (Super Root Key) table to be used to validate the code. There can be a table of maximum 8 public keys present in the header. The Secure Fuse Processor doesn't actually store a public key, it stores a SHA-256 hash of the table. If the hash of the SRK table fails to match the stored hash, secure boot fails.
5. **Signature validation**: With the validated public key, ISBC decrypts the digital signature stored with the CSF header. The ISBC then uses the PBI length field in the RCW to calculate a hash over all PBI commands (CSF header is also a part of PBI commands) along with the SRK table. Optional flags in the CSF header tell the ISBC whether the FSL Unique ID and the OEM Unique ID (in the Secure Fuse Processor) are to be checked or not. Including these IDs allows the image to be bound to a single platform. If the decrypted hash and generated hash don ' t match, secure boot fails.
6. **Sec_Mon Transition**: If ISS (Increment Security State) flag is set in the header, transition the SNVS state from Check to Trusted.

NOTE

1. PBI commands in Secure Boot must have a command '**Load Boot 1 CSF Header Ptr**' to inform the ISBC about location of CSF Header for BOOT1 image (ESBC).
2. Boot1 image and header must be placed on an XIP memory before execution of next phase (ISBC validation of Boot1/ESBC). If these images are placed on memories like NAND/SD/eMMC, then they must be copied to an XIP memory like OCRAM, DDR via PBI commands.

10.3.3.2.2 ISBC for Boot1 (Boot Loader 1) validation

1. **Valid header check**: Check for a valid preamble and correct B0/1 flag set as 1 in the header. If not, an error is raised.
2. **CSF parsing and public key check**: If ISBC finds a valid CSF header, it parses the CSF header to locate the public key from SRK (Super Root Key) table to be used to validate the code. There can be a table of maximum 8 public keys present in the header. The Secure Fuse Processor doesn't actually store a public key, it stores a SHA-256 hash of the table. If the hash of the SRK table fails to match the stored hash, secure boot fails.
3. **Signature validation**: With the validated public key, ISBC decrypts the digital signature stored with the CSF header. The image information is stored in a SG (scatter gather) table with support of up to 8 discrete images. The ISBC calculates a hash over the CSF header, SRK table, SG table and all entries in SG table (i.e. images). Optional flags in the CSF header tell the ISBC whether the FSL Unique ID and the OEM Unique ID (in the Secure Fuse Processor) are to be checked or not. Including these IDs allows the image to be bound to a single platform. If the decrypted hash and generated hash do not match, secure boot fails.
4. **Entry Point check**: One final check is performed by the ISBC. This check confirms that the Entry Point to be updated in Boot Location Pointer falls within one of the SG entries which have been validated by the ISBC.
5. **Sec_Mon Transition**: If ISS (Increment Security State) flag is set in the header, transition the SNVS state from Check to Trusted or Trusted (if transitioned in PB phase) to Secure.

NOTE

1. After End of ISBC, Entry Point parsed from header is written to Boot LOC PTR register.
2. GPP is waken up.
3. SP goes to sleep.

There are many reasons the ISBC could fail to validate the PBI or Boot1. Technicians with debug access can check the DCFG SCRATCHRW3 register to obtain an error code. For a list of error codes refer ISBC Validation Error Codes.

10.3.3.3 ESBC Phase

Unlike the ISBC, which is in an internal ROM and therefore unchangeable, the ESBC is reference code, and can be changed by OEMs. The remainder of this section is the description of a reasonable secure boot chain of trust based on NXP's reference software for secure boot. The reference ESBC code is also part of the Boot 1 image validated by ISBC and would be used to validate further ESBC images like MC, AIOP, and LINUX etc.

NXP provided ESBC consists of standard u-boot which has been signed using a private key. If the Boot Mode is secure, user can't reach to uboot prompt as the environment variable **bootdelay** is defined to 0.

There is default boot command for secure boot in the environment which executes on auto boot. This default **bootcmd** validates a file called boot script and on successful validation execute the commands in the boot script.

There are many reasons ESBC could fail to validate Client images or boot script. The error status message along with the code is printed on the u-boot console. For a list of error codes refer ESBC Validation Error Codes.

Users are free to use NXP ESBC as it is provided or to use it as reference to modify their own secure boot system.

To establish the Secure Boot Chain of Trust, some U-Boot Commands have been added in the ESBC Code which will be discussed in detail in coming sections.

10.3.3.3.1 esbc_validate command

```
esbc_validate img_hdr [pub_key_hash]
```

Input arguments:

img_hdr – Location of CSF header of the image to be validated

pub_key_hash – hash of the public key used to verify the image. This is optional parameter. If not provided, code makes the assumption that the key pair used to sign the image is same as that used with ISBC. So the hash of the key in the header is checked against the hash available in SRK fuse for verification.

Description:

The command would do the following:

Perform CSF header validation on the address passed in the image header. During parsing of the header, image address in stored in an environment variable which is later used in source command in default secure boot command.

Signature checks on the image.

10.3.3.3.2 esbc_halt command

```
esbc_halt (no arguments)
```

Description:

This command puts core in spin loop.

10.3.3.3.3 blob enc command

```
blob enc <src location> <dst location> <length> <key_modifier address>
```

Input Arguments:

src location	Address of the image to be encapsulated
dst location	Address where the blob will be created
length	Size of the image to be encapsulated
key_modifier address	Address where a random number 16 bytes long (key modifier) is placed

Description:

This command would create a cryptographic blob of the image placed at src location and place the blob at dst location.

10.3.3.3.4 blob dec command

```
blob dec <src location> <dst location> <length> <key_modifier address>
```

Input Arguments:

src location	Address of the image blob to be decapsulated
dst location	Address where the decapsulated image will be placed
length	Expected Size of the image after decapsulation
key_modifier address	Address where a random number 16 bytes long(key modifier) is placed

Description:

This command would decapsulate the blob placed at src location and place the decapsulated data of expected size at dst location.

10.3.3.3.5 Boot Script

Boot script is a U-Boot script image which contains u-boot commands. ESBC would validate this boot script before executing commands in it.

1. Boot script can have any commands which u-boot supports. No checking is done on the allowed commands in boot script. Since it is validated image, assumption is that commands in boot script would be correct.
2. If some basic scripting error is done in boot script like unknown command, missing arguments, the required usage of that command and core is put in infinite loop.
3. After execution of commands in boot script, if control reaches back in u-boot, error message would be printed on u-boot console and core would be put in spin loop by command esbc_halt.
4. Scatter gather images are not supported with validate command.
5. If ITS fuse is blown, any error in verification of the image would result in system reset. The error would be printed on console before system goes for a reset.

Where to place the boot script?

ESBC u-boot expects the boot script to be loaded in flash as specified in Address Map used for demo on page 2112. ESBC u-boot code assumes that the public/private key pair used to sign the boot script is same as that was used while signing the u-boot image. If user used different key pair to sign the image, hash of the N and E component of the key pair should be defined in macro:

```
CONFIG_BOOTSCRIPT_KEY_HASH
```

10.3.3.3.5.1 Chain of Trust

Boot script contains information about the next level images, e.g. MC, LINUX etc. ESBC validates these images as per their public keys. MC is started with validated MC images if required and finally bootm command is executed to pass control to LINUX image.

Users are free to use NXP ESBC as it is provided or to use it as reference to modify their own secure boot system. Figure below shows the Chain of Trust established for validation with this ESBC.

Sample Boot Script

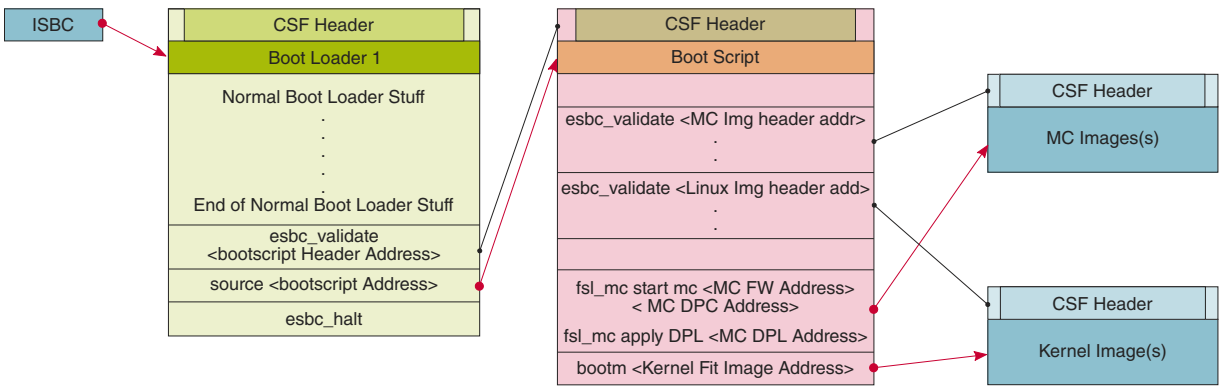

Figure 336. Secure Boot Flow (Chain of Trust)

```
# Get Images and Headers on DDR
.
.
.
# Validate the Images. (<pub_key_hash> is optional)
esbc_validate <Image1 Header Address> <pub_key_hash>
esbc_validate <Image2 Header Address> <pub_key_hash>
.
.
.
```

```
# Start MC with validated images
fsl_mc start mc <MC FW Address> < MC DPC Address>
fsl_mc apply DPL <MC DPL Address>

# Boot the Linux
bootm <Kernel Fit Image Address>
```

10.3.3.3.5.2 Chain of Trust with confidentiality

To establish chain of trust with confidentiality, cryptographic blob mechanism can be used. In this chain of trust, validated image is allowed to use the One Time Programmable Master Key to decrypt system secrets. Two bootscripts are to be used. First encap bootscripts is used which creates a blob of the next level images(e.g. MC, LINUX etc.) and saves them on flash. After this the system is booted after replacing the encap bootscript with decap bootscript which decapsulates the blobs and start MC and LINUX.

Sample Encap Boot Script

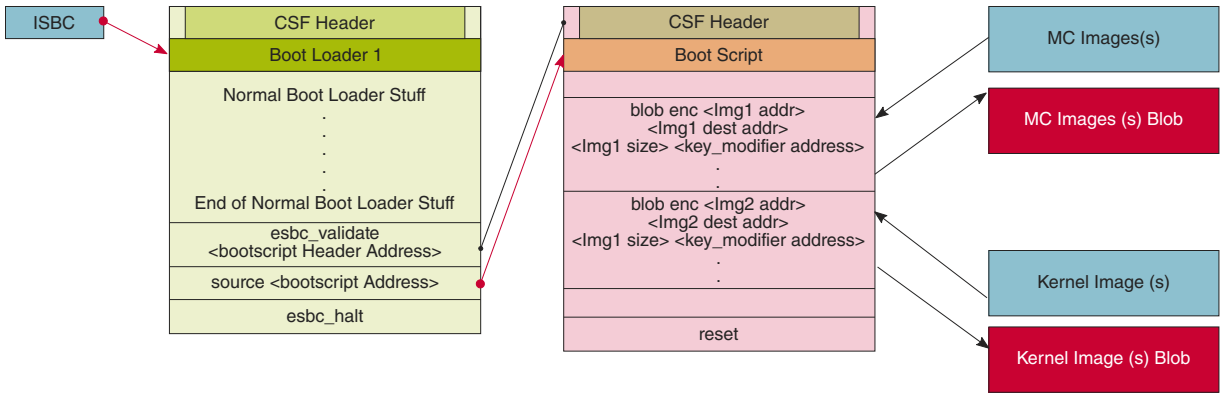

Figure 337. Chain of Trust with Confidentiality (Encapsulation)

```
# Get Images on DDR
.
.
.
# Create the Blobs
blob enc <Img1 addr> <Img1 dest addr> <Img1 size> <key_modifier address>
blob enc <Img2 addr> <Img2 dest addr> <Img2 size> <key_modifier address>
blob enc <Img3 addr> <Img3 dest addr> <Img3 size> <key_modifier address>
.
.
.

Save The Blobs created on Flash
.
.
.

# End of Encap Boot Script (This is one time only and must be replaced with decap Boot Script)
```

Sample Decap Boot Script

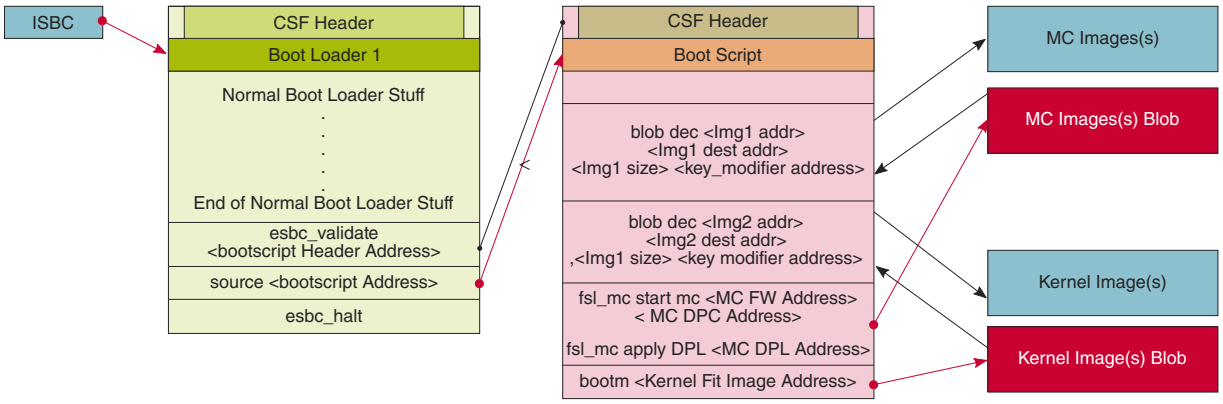

Figure 338. Chain of Trust with Confidentiality (Decapsulation)

```
# Get Images Blobs on DDR
.
.
.
# Decap the Blobs to get the actual images
blob dec <Img1 blob addr> <Img1 dest addr> <expected Img1 size> <key_modifier address>
blob dec <Img2 blob addr> <Img2 dest addr> <expected Img2 size> <key_modifier address>
blob dec <Img3 blob addr> <Img3 dest addr> <expected Img3 size> <key_modifier address>
.
.
.
# Start MC with validated images
fsl_mc start mc <MC FW Address> < MC DPC Address>
fsl_mc apply DPL <MC DPL Address>

# Boot the Linux
bootm <Kernel Fit Image Address>
```

10.3.3.4 Next Executable Phase

The bootloader (ESBC) finishes the platform initialization and passed control to the Linux image. The boot-chain can be further extended to be able to sign application which would be running on Linux prompt. Further RTIC can be integrated to verify memory regions using Security Engine (SEC) during run time.

10.3.3.5 ISBC Key Extension (IE)

The ISBC Key Extension feature allows the user to extend the number of keys available for signature validation. To use this feature, ISBC validates a table of **public** keys (IE keys) along with the ESBC image using one of the SRKs (Super Root Keys). These validated IE keys later become available for ESBC to use to validate downstream images e.g. Linux, MC etc.

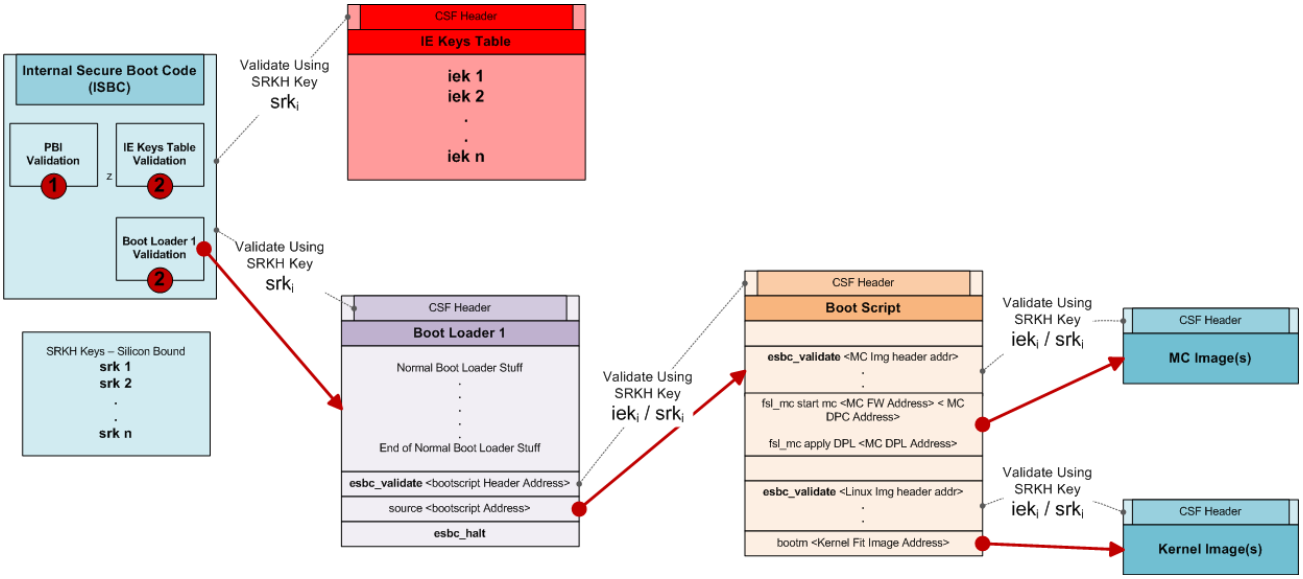

Figure 339. Secure Boot Flow (with IE)

As shown in the Secure Boot Flow (with IE),

1. ISBC code validates IE Table and Bootloader (ESBC) using one of the SRKs (Silicon Bound).
2. After IE Table is successfully validated, it becomes available for use by future images.[29](SRKs are present in SRK Table which is supplied with each image that is signed and validated using them. They are silicon bound as their hash, SRKH, is present in SoC's fuses.)
3. ESBC validates further images using either SRKs or IE Keys, which in turn can validate other images using these keys. Which key to use to verify image is decided based on CSF Header of the image to be validated.

The advantage of IE Keys is that

- Different images can be signed and validated using different IE keys. This is not possible with SRKs as they are significantly less in number than IE Keys.
- IE Key table can be changed as opposed to SRKs which are fixed as they are tied to SRKH blown in fuses.

10.3.3.5.1 IE Table Format

Table 376. Table: IE Table format

Offset (In Bytes)	Description
0x0 - 0x3	Keys Revoked. Each bit represents a key. If the bit is set, it indicates that this key in the table has been revoked and cannot be used for verification purposes. Bit 0 represents Key 1, Bit 1 represent Key 2 ..., Bit 31 represents Key 32.
0x04-0x07	Total number of keys present in the table (Max 32).
0x08-0x0b	Key 1 length (In bytes. Max 1024)

Table continues on the next page...

[29] For allowing ESBC image to use IE Table, it is neccesary for the IE Table to be present in an XIP memory. This is trivial in case of XIP memories such as NOR. In case on Non - XIP memories, IE table needs to be copied along with CSF Header to an XIP memory.

Table 376. Table: IE Table format (continued)

Offset (In Bytes)	Description
0x0c-0x40b	Key 1 value (Zero padded if less than 1024 bytes)
0x40c-0x40f	Key 2 length
0x410-0x80f	Key 2 value
.....	.....
0x8 + 0x404 * (n - 1) - 0x8 + 0x404 8 (n - 1) + 0x3	Key N length (N <= 32)
0x8 + 0x404 * (n - 1) + 0x4 - 0x8 + 0x404 * (n) - 0x1	Key N value

10.3.3.5.2 Enabling IE via CST Tool

The following are the steps that needs to be executed during **run-time** to enable use of IE feature during secure boot:

1. During PBI Phase, Scratch registers 13 and 14 (in DCFG Block) needs to be populated with the address of IE Table (to be loaded later). Scratch register 14 contains the higher 32 bits of address of IE Table and Scratch register 13 contains the lower 32 bits of address (SoC supports 48 bit address space).
2. Next, during the ISBC runtime, the IE table needs to be validated along with the ESBC image. For this, the address of this IE Table is added as the first entry in SG Table of CSF header.
3. Now ESBC can use either one of the IE Keys or the SRK Keys to validate next images. Which key to use, depends on the various field of CSF header (CSF Header Structure Definition on page 2096) of the image to be validated
   a. If IE Flag is not set, then one of the SRKs is used to verify the image. The key number is taken from the "Key No. for verification" flag. All SRKs would be present in the SRK Table, whose offset is embedded in CSF header.
   b. If IE Flag is set, then one of the IE Keys is used to verify the image. The key number is taken from the "IE Key Select" flag. The key is gathered from IE Table, the address of which was already populated in Scratch registers 13 and 14.

The following are the steps that needs to be executed during **build-time** to incorporate IE Table in CSF header and sign images using IE Keys using CST tool :

1. Using uni_sign, sign ESBC image and IE Table (uni_sign also generates IE Table using IE keys). uni_sign also prints the IE Table address.
2. Using uni_pbi generate PBI commands which also includes the commands to write the address of IE Table given by uni_sign to Scratch registers 13 and 14.
3. Sign next level images using one of the IE Keys / SRKs.

10.3.3.5.2.1 uni_sign on ESBC

Sample Input File for uni_sign

Table 377. Description of Fields in Input File

Field in Input File	Description
IE_KEY	Comma seperated list of names of files containing public keys (IE Keys)
IE_REVOC	Comma seperated list of key number that are to be revoked from IE Table
ESBC_HDRADDR	32 Bit address where generated header shall be placed

The above file is an example of input file for running uni_sign on ESBC image to enable use of IE Table. Presence of field 'IE_KEY' indicates to the CST tool to embed IE Table in the output header file. Field 'ESBC_HDRADDR' is needed to calculate address of IE Table. It states the address at which the output of uni_sign (output header file) will be placed on memory map. 'PUB_KEY=srk.pub' and 'PRI_KEY=srk.pri' indicates that SRK Key needs to be used to sign both ESBC and IE Table.

Note: Here ESBC_HDRADDR needs to be 32 bit address as ISBC can only access 32 bit addresses.

Output of uni_sign

```
$ ./uni_sign --verbose input_files/uni_sign/<platform>/ie_keys/input_uboot_nor_secure

Table 378. Description of Fields in Input File

Field in Input File	Description
IE_TABLE_ADDR	64 bit address of IE Table

As shown above, in the input file to uni_pbi, the field 'IE_TABLE_ADDR' is needed. This field indicates the address of IE Table, the address which is written to Scratch registers 13 and 14.

Note: This address (0x580020a00) is different from the address generated from uni_sign (0x30020a00) (though both address maps to same address. Refer to the memory map of the respective SoC). This is because ISBC can only access 32 bit addresses and u-boot uses only 48 bit addresses for NOR mapping because u-boot doesn't make MMU Table entries for the 32 bit addresses of NOR. So uni_sign needs 32 bit address so that ISBC can access this address to validate IE Table and uni_pbi needs 48 bit address so that u-boot can access the address written in the Scratch register 13 and 14 to fetch the keys in IE Table.

Output of uni_pbi

```
$ ./uni_pbi input_files/uni_pbi/<platform>/ie_keys/input_pbi_nor_secure

-------------------------------------------------
# Specify VERBOSE as 1, if you want to Display Header Information [Optional]
VERBOSE=0
```

Table 379. Description of Fields in Input File

Field in Input File	Description
IE_KEY_SEL	Number of the key in IE Table that is to be used to validate image

As shown above, in the input file to uni_sign, the field 'IE_KEY_SEL' indicates that a Key from IE Table is being used and it also indicates which key number from IE Table needs to be used to validate this image during run-time. For build-time, CST tool needs the IE private key. This is indicated via the field 'PRI_KEY'.

Output of uni_sign

```
$ ./uni_sign input_files/uni_sign/<platform>/ie_keys/input_kernel_secure

    #-------------------------------------------------------#
    #-------         --------     --------        -------#
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #-------------------------------------------------------#

============================================================
This tool includes software developed by OpenSSL Project
for use in the OpenSSL Toolkit (http://www.openssl.org/)
This product includes cryptographic software written by
Eric Young (eay@cryptsoft.com)
============================================================

Input File is input_files/uni_sign/<platform>/ie_keys/input_kernel_secure

SRK/Public Key Hash not calculated.. IE = 1

***********************************************
* Header File is with Signature appended
***********************************************

Header File Created: hdr_kernel.out
SRK (Public Key) Hash Not Available
```

As shown above, SRK Hash is not calculated as IE Key is being used.

10.3.3.6 Product Execution

This section presents the steps to be followed in order to properly run the software product according to its intended use and functionalities.

Steps in the demo would be:

1. ISBC code would validate PBI and Boot Loader 1.
2. On Successful validation, PBI commands would be executed by SP BootROM.
3. Boot Loader 1 execution will begin on GPP.
4. The ESBC code in Boot Loader 1 would validate and execute and bootscript.[30]
5. The boot script would contain the commands to validate and execute next level images as described in Boot Script on page 2071Boot Script on page 2071.

10.3.3.6.1 Environment for Secure Boot

There are 2 ways in which secure boot can be initiated:

1. Set SB_EN bit in RCW to 1.
2. Programming the ITS fuse in SFP.

In a manufacturing environment, it is recommended that all fuses be programmed at once, including the ITS and OEM Section Write Protect bits. In a prototyping environment, it may be preferable to leave ITS and Write Protect unprogrammed (relying on RCW to initiate secure boot) until the developer has confidence in the secure boot process.

10.3.3.6.2 SDK images required for demo

Given Below are the images required which are built as part of the SDK Release:

1. RCW along with PBI commands
2. Boot Loader Image(s[31])
3. Kernel Fit Image
4. MC/AIOP image(s)[32]

10.3.3.6.3 CST tool for signing images

CST tool used for signing the images is provided as a package with yocto and is built for host. It can be run from your host machine.

Install path for CST binaries in yocto:

```
tmp/sysroots/x86_64-linux/usr/bin/cst/
```

In the Yocto environment, the user needs to use below commands to rebuild CST:

1. Modify the CST source code if needed
2. bitbake cst-native –c cleanall
3. bitbake cst-native

[30] In case the boot loader is split into two parts, the validation and execution of boot script would happen in the final boot loader i.e Boot Loader2. Boot Loader 1 will validate and transfer control to Boot Loader 2.
[31] In Case the Boot Loader is split into parts.
[32] MC/AIOP loading is optional and can be skipped.

NOTE

1. Sample Input Files are provided in the CST package for signing the various images and creating the headers as per the memory map described in Address Map used for demo on page 2112
2. The input files also contain the names of the images to be signed and names of output header file. User must place the images with the same name as specified in input file in the CST directory.
3. If a custom name/address is desired, then the same must be specified in the input file before executing the CST tool.

Table 380. CST Input File Information

Image	CST Tool	Image Name in Input File	Output Name in Input File
RCW with PBI commands	uni_pbi	rcw.bin	rcw_sec.bin
U-Boot	uni_sign (ESBC=0)	u-boot-dtb.bin	hdr_uboot.out
BootScript	uni_sign (ESBC=1)	bootscript	hdr_bs.out
Linux Kernel Image	uni_sign (ESBC=1)	kernel.itb	hdr_kernel.out
Management complex Firmware(MC)	uni_sign (ESBC=1)	mc.itb	hdr_mc.out
MC DPL	uni_sign (ESBC=1)	dpl.itb	hdr_dpl.out
MC DPC	uni_sign (ESBC=1)	dpc.dtb	hdr_dpc.out
PPA	uni_sign (ESBC=1)	ppa.itb	hdr_ppa.out

10.3.3.6.4 Chain of Trust

This section presents the steps needed to be followed in order to execute Chain of Trust.

10.3.3.6.4.1 Other images required for demo

Apart from SDK images described above, the following images are also required:

1. rcw_sec.bin (Contains the CSF Header for PBI commands. This is created using **uni_pbi** CST Tool)
2. CSF header for Boot Loader 1. (Created using **uni_sign** CST tool with **ESBC = 0**)
3. CSF header of Kernel Image (Created using **uni_sign** CST tool with **ESBC = 1**)
4. Boot Script
5. CSF header of Boot Script (Created using **uni_sign** CST tool with **ESBC = 1**)
6. Optional: (Created using **uni_sign** CST tool with **ESBC = 1**)
   a. CSF header(s) for MC/AIOP image(s).
   b. CSF header(s) for Boot Loader 2..n.

10.3.3.6.4.2 Boot Script and signing images

CSF header needs to be generated for all the images. More details on the commands provided by CST can be found in Code Signing Tool on page 2116

Signing images using same key pair

1. Generate the public/private key pair to be used for signing the image

```
./gen_keys 1024
```

   Key pair - public key file - srk.pub and private key in srk.priv would be generated.

2. Copy all the required images in the CST directory with the names as specified in the Input Files (Table 380. CST Input File Information on page 2085)
3. Create CSF header for PBI and U-Boot Image.

```
./uni_pbi input_files/uni_pbi/<platform>/input_pbi_nor_secure
```

```
./uni_sign input_files/uni_sign/<platform>/input_uboot_nor_secure
```

   Executing the above command would also output a 256 bit hash of the SRK Table. This has to be programmed in the SRKF fuses in SFP. The hash can also be obtained later on by using the command

```
./uni_sign --hash <input_file>
```

NOTE

a. The steps in demo are described for NOR Boot. The input files chosen above have the corresponding address from NOR Flash.

b. For the ESBC images, the images are first copied to DDR and then validated. Thus the input files and corresponding output headers would have addresses of DDR and the input files are independent of the boot source.

4. Create CSF header for Linux Kernel Image.

```
./uni_sign input_files/uni_sign/<platform>/input_kernel_secure
```

5. Create header for PPA using PPA input file as ./uni_sign input_files/uni_sign/<platform>/input_ppa_secure
6. Create CSF header(s) for MC Image(s) if required.

```
./uni_sign input_files/uni_sign/<platform>/input_mc_secure
./uni_sign input_files/uni_sign/<platform>/input_dpl_secure
./uni_sign input_files/uni_sign/<platform>/input_dpc_secure
```

7. Create the Boot Script (Chain of Trust on page 2072) using the following steps:

   a. Create a text file bootscript.txt with following commands:

NOTE

- The commands to get the images on DDR would change if the headers and images are placed on some other device like NAND or SD.
- The other commands for validation and booting remain same irresepctive of the device.
- The address and size of image(s) are as specified in Address Map used for demo on page 2112

```
#Get All ESBC Headers on DDR
#LINUX Kernel Header
cp.b 0x580d80000 0xa0d80000 0x4000;
#DPL Header
cp.b 0x580d40000 0xa0d40000 0x4000;
```

```
#Get All ESBC Images on DDR
#LINUX Kernel Image
cp.b 0x581100000 0xa1100000 0x2800000;
#DPL Image
cp.b 0x580700000 0xa0700000 0x100000;
```

```
###Validating DPL###
esbc_validate 0xa0d40000;
setenv dpl_img $img_addr;

fsl_mc apply DPL $dpl_img

###Validate and Boot Kernal Image###
echo "Validating Kernel"
esbc_validate 0xa0d80000
bootm $img_addr;
```

b. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A arm -T script -a 0 -e 0x40 -d bootscript.txt
bootscript
```

8. Create CSF header for Boot Script.

```
./uni_sign input_files/uni_sign/<platform>/input_bootscript_secure
```

Signing images using different key pair

U-Boot and PBI must be signed with the same key pair as they are both validated by ISBC. For all ESBC images a different key pair can be used if desired.

NOTE

If boot script is also signed with a different key, remember to define the macro "CONFIG_BOOTSCRIPT_KEY_HASH" with the hash of the key used to sign the boot script in file:

```
include/config_fsl_chain_trust.h
```

1. Generate the public/private key pair to be used for signing the image

```
./gen_keys 1024 -p isbc.priv -k isbc.pub
```

Key pair - public key file - isbc.pub and private key in isbc.priv would be generated.

2. Copy all the required images in the CST directory with the names as specified in the Input Files (Table 380. CST Input File Information on page 2085)
3. Create CSF header for PBI and U-Boot Image.

Change PRI_KEY and PUB_KEY to isbc.priv and isbc.pub respectively in the input files.

```
./uni_pbi input_files/uni_pbi/<platform>/input_pbi_nor_secure
```

```
./uni_sign input_files/uni_sign/<platform>/input_kernel_secure
```

Executing the above command would also output a 256 bit hash of the SRK table. This has to be programmed in the SRKF fuses in SFP. The hash can also be obtained later on by using the command

```
./uni_sign --hash <input_file>
```

NOTE

a. The steps in demo are described for NOR boot. The input files chosen above have the corresponding address from NOR flash.

b. For the ESBC images, the images are first copied to DDR and then validated. Thus the input files and corresponding output headers would have addresses of DDR and the input files are independent of the boot source.

4. Repeat step 1 to generate more key pair(s) for other ESBC images

```
./gen_keys 1024 -p bootscript.priv -k bootscript.pub
./gen_keys 1024 -p kernel.priv -k kernel.pub
./gen_keys 1024 -p mc.priv -k mc.pub
./gen_keys 1024 -p dpc.priv -k dpc.pub
./gen_keys 1024 -p dpl.priv -k dpl.pub
```

5. Create CSF header for Linux Kernel Image.

   Change PRI_KEY and PUB_KEY to kernel.priv and kernel.pub respectively in the input files.

```
./uni_sign input_files/uni_sign/<platform>/input_kernel_secure
```

   The key hash obtained is <kernel_key_hash>

6. Create header for PPA using PPA input file as ./uni_sign input_files/uni_sign/<platform>/input_ppa_secure

7. Create CSF header(s) for MC image(s) if required.

   Change PRI_KEY and PUB_KEY to corresponding key names in the input files.

```
./uni_sign input_files/uni_sign/<platform>/input_mc_secure
./uni_sign input_files/uni_sign/<platform>/input_dpl_secure
./uni_sign input_files/uni_sign/<platform>/input_dpc_secure
```

   The key hash(s) obtained will be <mc_key_hash>, <dpl_key_hash> and <dpc_key_hash>

8. Create the Boot Script (Chain of Trust on page 2072) using the following steps:

   a. Create a text file bootscript.txt with following commands:

NOTE

- The commands to get the images on DDR would change if the headers and images are placed on some other device like NAND or SD.
- The other commands for validation and booting remain same irresepctive of the device.
- The address and size of image(s) are as specified in Address Map used for demo on page 2112

```
#Get All ESBC Headers on DDR
#LINUX Kernel Header
cp.b 0x580d80000 0xa0d80000 0x4000;
#DPL Header
cp.b 0x580d40000 0xa0d40000 0x4000;
```

```
#Get All ESBC Images on DDR
#LINUX Kernel Image
cp.b 0x581100000 0xa1100000 0x2800000;
#DPL Image
cp.b 0x580700000 0xa0700000 0x400000;
```

```
###Validating DPL###
echo "Validating DPL"

esbc_validate 0xa0d40000 <dpl_key_hash>
setenv dpl_img $img_addr;

fsl_mc apply DPL $dpl_img

###Validate and Boot Kernal Image###
echo "Validating Kernel"
esbc_validate 0xa0d80000 <kernel_key_hash>
bootm $img_addr;
```

b. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A arm -T script -a 0 -e 0x40 -d bootscript.txt
bootscript
```

9. Create CSF header for Boot Script.

   Change PRI_KEY and PUB_KEY to bootscript.priv and bootscript.pub respectively in the input files.

```
./uni_sign input_files/uni_sign/<platform>/input_bootscript_secure
```

10.3.3.6.4.3 Running Secure Boot (Chain of Trust)

1. Setup the board for secure boot flow. You can choose any if the flows mentioned below.
   a. **Flow A**

      Program the ITS fuse.

   b. **Flow B**

      For protyping phase, don't blow the ITS fuse, Secure Boot can be enabled by RCW with SB_EN = 1.
2. Blow other required fuses(OTPMK and SRK Hash[33]) in the SFP in silicon. For more details regarding fuse blowing, CCS and Reset Pause, refer to *Platform Reference Manual* and *Trust Architecture User Guide*.

[33] Blowing of OTPMK is essential to run secure boot for both Production (Flow A) and Prototyping/ Development (Flow B).

For SRK Hash,in Development Mode (Flow B), there is a workaround to avoid blowing fuses. The SoC can be put in a **Reset Pause** state. This will pause the Reset State Machinery after RCW Loading. Then CCS can be connected via JTAG.

Write the SRK Hash value in SFP mirror registers and then get the system out of Reset Pause State.

NOTE

SRK hash in the fuse should be same as the hash of the key pair being used to sign the PBI and U-Boot image.

For testing purpose, the SRK hash can be written in the mirror registers.

gen_otpmk_drbg utility in CST can be used to generate otpmk key.

3. Flash all the generated images at locations as described in the address map(Address Map used for demo on page 2112).
   a. **Flow A** - All the images would have to be flashed at the current bank addresses.
   b. If you are using **Flow B**, you can use alternate bank for demo purpose. This would mean flashing the images on alternate bank addresses from Bank0 and then switching to Bank4.

NOTE

The U-Boot commands to flash the images as per the address map and CCS info are described in Useful Commands on page 2113.

4. Give a power on cycle to the board.
   a. For Flow A and Flow B (If Secure Boot images flashed on default bank)
      - On power on, ISBC code in SP Boot ROM would validate the PBI image followed by validation of Boot Loader1 (U-Boot)
      - ESBC code in Boot Loader 1 image would further validate the ESBC images (BootScript, LINUX, MC etc.)
      - MC and LINUX would be started.
   b. For Flow B (If Secure Boot images flashed on alternate bank), the user must first do the switch settings[34] for booting from alternate bank and also to enable reset pause.
      - On power on after the correct switch setting, Reset State Machinery will be paused after RCW loading.
      - Write the SRKH to SFP mirror registers and get the system out of Reset Pause via CCS.
      - Secure Boot flow as mentioned above would execute.

10.3.3.6.5 Chain of Trust with confidentiality

This section presents the steps to be followed in order to execute chain of trust with confidentiality.

The demo would be divided into two parts:

1. Creating /encrypting images in form of blobs.
2. Decrypting the images, and booting from decrypted images.

The execution steps remain same as specified above in Product Execution on page 2084. In first phase the Boot Script would contain the commands to encrypt and create blobs of the images. After that the Boot Script is replaced and in second phase the Boot Script would contain commands to decrypt the blobs to get back the images and boot LINUX, AIOP using these images.

10.3.3.6.5.1 Other images required for demo

Apart from SDK images described above, the following images are also required:

1. rcw_sec.bin (contains the CSF header for PBI commands. This is created using **uni_pbi** CST tool)
2. CSF header for Boot Loader 1. (Created using **uni_sign** CST tool with **ESBC = 0**)
3. Encap Boot Script

[34] This may also be done via writing to FPGA registers from the U-Boot Prompt of U-Boot runing in Non-Secure Mode on Bank0. Please refer the Platform FPGA guide for the same.

4. Decap Boot Script
5. CSF header of Encap Boot Script (Created using **uni_sign** CST tool with **ESBC = 1**)
6. CSF header of Decap Boot Script (Created using **uni_sign** CST tool with **ESBC = 1**)
7. **[Optional]** CSF header(s) for Boot Loader 2..n.(Created using **uni_sign** CST tool with **ESBC = 1**)

10.3.3.6.5.2 Boot Script and signing images

NOTE

- The commands to get the images on DDR would change if the images are placed on some other device like NAND or SD.
- The other commands for encryption, decryption and booting remain same irresepctive of the device.
- The address and size of image(s) are as specified in Address Map used for demo on page 2112

Encap Boot Script

1. Create a bootscript_en.txt file with following commands:
2. For device specific bootscript_en.txt refer in section (LS1088: Secure Boot Demo) Address Map used for demo on page 2112

```
#Sample Encap Bootscript
#Makes blob of Linux, MC,DPL,DPC images and replace original images
#with blobs
#Addr for DRAM to use temporarily
setenv dram_temp "0x80000000"
setenv dram_temp2 "0xa0000000"
#Write Key
mw 0x90000000 0x1234567
mw 0x90000004 0x1234567
mw 0x90000008 0x1234567
mw 0x9000000c 0x1234567
#Key Identifier Addr
setenv key_id_addr "0x90000000"
#Encap MC
cp.b 0x580300000 $dram_temp2  0x3c0000
blob enc $dram_temp2 $dram_temp 0x3c0000 $key_id_addr
erase 0x580300000 +0x400000
cp.b $dram_temp 0x580300000 0x400000
#Encap DPL
cp.b 0x580700000 $dram_temp2  0xc0000
blob enc $dram_temp2 $dram_temp 0xc0000 $key_id_addr
erase 0x580700000 +0x100000
cp.b $dram_temp 0x580700000 0x100000
#Encap DPC
cp.b 0x580800000 $dram_temp2  0xc0000
blob enc $dram_temp2 $dram_temp 0xc0000 $key_id_addr
erase 0x580800000 +0x100000
cp.b $dram_temp 0x580800000 0x100000
#Encap Kernel
cp.b 0x581100000 $dram_temp2  0x27c0000
blob enc $dram_temp2 $dram_temp 0x27c0000 $key_id_addr
erase 0x581100000 +0x2800000
cp.b $dram_temp 0x581100000 0x2800000
```

3. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A arm -T script -a 0 -e 0x40 -d bootscript_en.txt
bootscript_encap
```

Decap Boot Script

1. Create a bootscript_de.txt file with following commands:
2. For device specific bootscript_de.txt refer to section (LS1088: Secure Boot Demo) Address Map used for demo on page 2112

```
# Sample Decap Boot Script
#Decrypt blob of Linux, MC,DPL,DPC images to get original images
#Write Key - Same as key for Enc
mw 0x90000000 0x1234567
mw 0x90000004 0x1234567
mw 0x90000008 0x1234567
mw 0x9000000c 0x1234567
#Key Identifier Addr
setenv key_id_addr "0x90000000"
#Addr for DRAM to use temporarily
setenv dram_temp "0x80000000"
#Decrypt MC
cp.b 0x580300000 $dram_temp 0x400000
blob dec  $dram_temp 0xa0300000 0x3c0000 $key_id_addr
#Decrypt DPL
cp.b 0x580700000 $dram_temp 0x100000
blob dec $dram_temp 0xa0700000 0xc0000 $key_id_addr
#Decrypt DPC
cp.b 0x580800000 $dram_temp 0x100000
blob dec $dram_temp 0xa0800000 0xc0000 $key_id_addr
#Decrypt Kernel
cp.b 0x581100000 $dram_temp 0x2800000
blob dec $dram_temp 0xa1100000 0x27c0000 $key_id_addr
#Start MC
fsl_mc start mc 0xa0300000 0xa0800000;
fsl_mc apply DPL 0xa0700000
#Start Kernel
bootm 0xa1100000;
```

3. Use the mkimage tool to convert this text file into a U-Boot image (using the image type script)

```
/tmp/sysroots/x86_64-linux/usr/bin/mkimage -A arm -T script -a 0 -e 0x40 -d bootscript_de.txt
bootscript_decap
```

Signing the images

1. Generate the public/private key pair to be used for signing the image

```
./gen_keys 1024
```

   Key pair - public key file - srk.pub and private key in srk.priv would be generated.

2. Copy all the required images in the CST directory with the names a specified in the Input Files Address Map used for demo on page 2112

3. Create CSF header for PBI and U-Boot Image.

```
./uni_pbi input_files/uni_pbi/<platform>/<device>[35]/input_pbi_nor_secure
```

```
./uni_sign input_files/uni_sign/<platform>/<device>[36]/input_uboot_secure
```

Executing the above command would also output a 256 bit hash of the SRK table. This has to be programmed in the SRKF fuses in SFP. The hash can also be obtained later on by using the command

```
./uni_sign --hash <input_file>
```

4. Create CSF headers for both the Boot Scripts

Change the image name and output header name in the input file for the two bootscripts.

```
./uni_sign input_files/uni_sign/<platform>/<device>/input_bootscript_secure
```

10.3.3.6.5.3 Running Secure Boot (Chain of Trust with confidentiality)

1. Setup the board for secure boot flow. You can choose any if the flows mentioned below.
   a. **Flow A**

      Program the ITS fuse.

   b. **Flow B**

      For protyping phase, don't blow the ITS fuse, Secure Boot can be enabled by RCW with SB_EN = 1.

2. Blow other required fuses(OTPMK and SRK hash[37]) in the SFP in silicon. For more details regarding fuse blowing, CCS and Reset Pause, refer to Platform Reference Manual and Trust Architecture User Guide.

> **NOTE**
>
> SRK hash in the fuse should be same as the hash of the key pair being used to sign the PBI and U-Boot image.
>
> For testing purpose, the SRK hash can be written in the mirror registers.
>
> gen_otpmk_drbg utility in CST can be used to generate otpmk key.

3. Flash all the generated images at locations as described in the address map (Address Map used for demo on page 2112).
   - rcw_sec.bin
   - U-Boot binary
   - CSF header for U-Boot
   - Kernel fit image

---

[35] Device folder is not required in case of NOR device, for others use device name eg. qspi.

[36] Device folder is not required in case of NOR device, for others use device name eg. qspi.

[37] Blowing of OTPMK is essential to run secure boot for both Production (Flow A) and Prototyping/ Development (Flow B).

For SRK Hash,in Development Mode (Flow B), there is a workaround to avoid blowing fuses. The SoC can be put in a **Reset Pause** state. This will pause the Reset State Machinery after RCW Loading. Then CCS can be connected via JTAG.

Write the SRK Hash value in SFP mirror registers and then get the system out of Reset Pause State.

- MC, DPL, DPC images
- bootscript_encap
- CSF header for bootscript_encap

a. **Flow A** - All the images would have to be flashed at the current bank addresses.

b. If you are using **Flow B**, you can use alternate bank for demo purpose. This would mean flashing the images on alternate bank addresses from Bank0 and then switching to Bank4.

NOTE

The U-Boot commands to flash the images as per the address map and CCS info are described in Useful Commands on page 2113.

4. Give a power on cycle to the board.
   a. For Flow A and Flow B (If Secure Boot images flashed on default bank)
      - On power on, ISBC code in SP Boot ROM would validate the PBI image followed by validation of Boot Loader1 (U-Boot)
      - ESBC code in Boot Loader 1 image would further validate the Boot Script.
      - Boot Script would encapsulate the Kernel and MC images and store the blobs at the desired locations.
   b. For Flow B (If Secure Boot images flashed on alternate bank), the user must first do the switch settings[38] for booting from alternate bank and also to enable Reset Pause.
      - On power on after the correct switch setting, Reset State Machinery will be paused after RCW loading.
      - Write the SRKH to SFP mirror registers and get the system out of reset pause via CCS.
      - Secure Boot flow as mentioned above would execute.
5. Replace the encap bootscript and its CSF header with decap bootscript and the CSF header of the decap bootscript respectively.
6. Give a power on cycle to the board.
   a. For Flow A and Flow B (If Secure Boot images flashed on default bank)
      - On power on, ISBC code in SP Boot ROM would validate the PBI image followed by validation of Boot Loader1 (U-Boot)
      - ESBC code in Boot Loader 1 image would further validate the Boot Script.
      - Boot Script would decapsulate the Kernel and MC blobs and store the images on DDR.
      - MC and LINUX Kernel would be started.
   b. For Flow B (If Secure Boot images flashed on alternate bank), the user must first do the switch settings[39] for booting from alternate bank and also to enable Reset Pause.
      - On power on after the correct switch setting, Reset State Machinery will be paused after RCW Loading.
      - Write the SRKH to SFP mirror registers and get the system out of reset pause via CCS.
      - Secure Boot flow as mentioned above would execute.

[38] This may also be done via writing to FPGA registers from the U-Boot Prompt of U-Boot runing in Non-Secure Mode on Bank0. Please refer the Platform FPGA guide for the same.
[39] This may also be done via writing to FPGA registers from the U-Boot Prompt of U-Boot runing in Non-Secure Mode on Bank0. Please refer the Platform FPGA guide for the same.

10.3.3.7 PBI Structure

	Fields	Offset	Size (In 32-bit word)
RCW	Preamble (RCW)	0x00	1
	Load RCW Command	0x04	1
	RCW words	0x08 – 0x87	32
	RCW Checksum	0x88	1
PBI Commands	Load Security Header CSF Header	0x8c 0x90 – 0xdf	1 20
	Load Boot 1CSF Header Boot 1 pointer	0xe0 0xe4	1 1
	Other PBI Commands	0xe8	N
	STOP Command (With/ Without CRC)	0xe8 + (4*N)	2
SRK Table	SRK Table	0x90 + SRK table offset in CSF Header	(No. of Keys * Key length)
RSA signature	Signature	0x90 + Sign offset in CSF Header	Sign Length

RCW

Preamble The preamble is always the first element in a PBI Image. It contains a standard pattern that identifies the memory location as the beginning of a valid PBI Image. The preamble is a 4-byte pattern defined as “0xaa55aa55”.

Load RCW Command The next word is load RCW command. This command loads the 1024 bit Reset Configuration Word from the interface specified by Power-on-Reset (POR) Configuration strapping pins. It has two formats:

1. Load RCW with Checksum (0x10): Read Reset Configuration Word performs simple 32-bit checksum, and update RCW registers.
2. Load RCW without Checksum (0x11): Read Reset Configuration Word and update RCW registers without performing checksum. The version without the checksum includes padding with zeroes in the place of the checksum value.

RCW Words 1024 RCW bits i.e. 32 words of 32 bit.

RCW Checksum It is calculated as a 32-bit unsigned integer summation of the RCW Preamble, the Load RCW with checksum command, and each of the 32 words (32-bit) of the RCW. A simple 32-bit checksum is used for the validation of the command.

```
checksum(RCW_WORD[]){
    unsigned_32 sum = 0xAA55AA55 + 0x80100000 + Load RCW Command;
    for(i=0; i<32; i++)
        sum+=RCW_WORD[i];
```

```
    return (sum);
}
```

NOTE

Checksum will have to be updated by CST tool as the fields like SB_EN, PBI_LEN in the RCW words are changed.

PBI Commands	**Load Security Header**	This command loads information required for authentication of the PBI image. The security header includes pointers to an SRK key table and RSA signatures as well as other flags and IDs. The CSF Header is part of the command. Please refer the CSF header structure in .
	Load Boot 1 CSF Header	This command loads a pointer to a CSF Header used for authentication of the Boot 1 Secondary Program Loader. This 32-bit value used by the Boot 0 ISBC and is required for secure boot.
	Other PBI commands	Other PBI commands input by user.
	STOP Command	This command ends the PBI sequence and has two variants (with and without CRC). The CRC check value covers all commands from the first command after the RCW up to and including this CRC and Stop command, regardless of whether any are skipped by Jump commands during execution. In Stop command without CRC it ends the PBI sequence immediately. It does not include a CRC value, but it instead has a 32-bit padding with zeroes so that it is the same size as the Stop with CRC command.

NOTE

CST tool updates the PBI commands by adding Load Security Header command and Load Boot 1 Security Header command. So, CRC must also be updated.

SRK Table	Table of Public Keys used in Secure Boot Validation. It is kept at an offset from CSF Header. The offset is specified in the CSF Header.
RSA Signature	RSA signature calculated over all PBI commands and SRK Table. It is kept at an offset from CSF Header. The offset is specified in the CSF Header.

10.3.3.8 CSF Header Structure Definition

Table 381. Trust Architecture and SFP Information

SoC	Trust Arch. Version	SFP Version	POVDD	DRVR		OTPMK	
				Algo (CST)	Register to check Hamming Error	Algo (CST)	Register to check Hamming Error
LS1088A	3.1	3.5	1.89 V	A2	SFP Secret Value Hamming	2	SFP Secret Value Hamming

Figure 340. CSF Header Structure

Table 382. CSF Header Structure (ISBC Trust 3.0)

Offset	Description
0x00	**Barker Code** Fixed value which the ISBC uses to confirm it has located the start of a CSF header. (12_19_20_01) 0x00 – 0x12 0x01 – 0x19 0x02 – 0x20 0x03 – 0x01 It is numeric encoding of LSTA (LS Series Trust Architecture)

Table continues on the next page...

Table 382. CSF Header Structure (ISBC Trust 3.0) (continued)

Offset		Description
0x04		**SRK table offset** This location contains an address which is the offset of the SRK table from the start of CSF header. Using this offset and the number of entries is SRK table, the SRK table is read. * Description of fields in SRK Table is mentioned below.
0x08	0x08	**No. of keys** This field specifies the no. of keys in the SRK table
	0x09	**Key No. for verification** Key # to use for verification; the key in the table which the ISBC uses to attempt signature verification
	0x0a	Field Reserved
	0x0b	**IE :** Reserved **MP :** Execute Manufacturing Protection Routine **ISS :** Increment Security State; indicates whether the ISBC should increment the SNVS SSM upon successful verification **B01 :** Identifies whether this is the CSF header of a boot 0 image (PBI) or a boot 1 image (SPL) **LW :** Leave Writeable; when set; ISBC doesn't set the SFP Write Disable
0x0C	0x0C	Reserved
	0x0D	Reserved
	0x0E	Reserved
	0x0F	**OIDx**: when set, the corresponding OEM UID field in the SFP is included in the digital signature verification. For each bit set, the corresponding OUID field is included in the CSF header. **FUID** : when set, the 64b FUID is included in the digital signature verification and the FUID is included in the CSF header Other bits are reserved.
0x10		**RSA signature offset** This location contains an address which is the offset of the RSA signature from the start of CSF header. Using this offset and the Signature length, the RSA signature is read. The RSA signature is calculated over CSF Header, Scatter Gather table and ESBC images.
0x14		**RSA signature length** This location contains the length of the RSA Signature in bytes.
0x18		**SG table offset** This location contains an address which is the offset of the SG table from the start of CSF header. Using this offset and the number of entries is SG Table, the SG table is read. * Description of fields in SG table is mentioned below/.

Table continues on the next page...

Table 382. CSF Header Structure (ISBC Trust 3.0) (continued)

Offset	Description
0x1C	**No. of entries** This field specifies the number of entries present in SG table.
0x20	**Entry point (32 bit)** ISBC transfers control to this location upon successful validation of ESBC image(s).
0x24	FSL UID 0
0x28	FSL UID 1

10.3.3.9 Secure Boot Specific RCW Fields

This section describes the various fields in RCW which are relevant to the ISBC code executed in the Service Processor Boot ROM.

SB_EN Secure Boot Enable

Bit(s): 266

- 0 Secure Boot is not enabled[40]
- 1 Secure Boot is enabled

PBI_LENGTH Pre-Boot Initialization Length

Bit(s): 287-276

Size in words of the PBI commands.

SDBGEN Secure Debug Enable

Bit(s): 288

Secure Debug (CoreSight SPIDEN) is enabled after RCW is loaded if this RCW bit is set and the 'Intent to Secure' fuse value is cleared.

- 0 Secure debug is not enabled
- 1 Secure debug is enabled if the ITS fuse is not burned to asserted

GPIO_LED_EN GPIO LED Enable

Bit(s): 311

If the OEM chooses to implement a LED to indicate secure boot failure, the LED will be connected to a GPIO. The SP Boot ROM code sequence turns on the LED (if RCW[GPIO_LED_EN] = 1) by configuring

[40] Secure Boot is enabled if either this RCW bit is set or the Intent to Secure fuse value is set.

one GPIO direction (GPDIR) register bit as an output and writing the corresponding output in a GPIO block data (GPDAT) register.

GPIO_LED_NUM GPIO Number for LED

Bit(s): 310-304

If GPIO_LED_EN is set, these bits specify the GPIO number to which LED is connected.

- 0x1f - 0x00 : GPIO_1
- 0x3f - 0x20 : GPIO_2
- 0x5f - 0x40 : GPIO_3
- 0x7f - 0x60 : GPIO_4

NOTE

The GPIO output assigned to the LED is driven high to whatever VDD voltage is supplied by the integrated device for the chosen GPIO output.Since GPIO pins at the time of SoC reset are initially configured as inputs, and since there will be some indeterminate period of time from the assertion of SoC reset to when the GPIO pin is configured by SP Boot ROM as an output, the GPIO pin chosen must be terminated with a weak pulldown to ground.

10.3.3.10 ISBC Error Codes

Error Handling in Production Environemnt (ITS = 1)

- Error Code would be logged in DCFG SCARTCH register.
- SNVS would be transitioned to **soft fail** state.
- Activate the LED. If the OEM chooses to implement a LED to indicate secure boot failure, the LED will be connected to a GPIO. The information of GPIO is specified via bits in RCW.

  GPIO_LED_EN Bit(s): 311

  The SP Boot ROM code sequence turns on the LED (if RCW[GPIO_LED_EN] = 1) by configuring one GPIO direction (GPDIR) register bit as an output and writing the corresponding output in a GPIO block data (GPDAT) register.

  GPIO_LED_NUM Bit(s): 310-304

  If GPIO_LED_EN is set, these bits specify the GPIO number to which LED is connected.

  - 0x1f - 0x00 : GPIO_1
  - 0x3f - 0x20 : GPIO_2
  - 0x5f - 0x40 : GPIO_3
  - 0x7f - 0x60 : GPIO_4

- Soft Reset would be issued
- Cores would then enter infinite loop (If Reset is disabled)[41]

Error Handling in Development Environemnt (ITS = 0, SB_EN = 1)

- Error Code would be logged in DCFG SCARTCH register.
- SNVS would be transitioned to **non-secure** state.

[41] To debug the root cause of failure and view the error code, Reset has to be disabled on the SoC.

- Further actions depends on the type of failure

Fatal Errors Core is put in infinite Loop

Non-Fatal Error Application Software is allowed to execute

Error Codes

The Error codes reported by SP Boot ROM can be categorized in following sections:

1. Core Exceptions
2. Device Errors
3. RCW/PBI Errors
4. Validation Errors

Table 387. ISBC Error Codes

When Error Generated	Error Code	Value	Description
Core Exceptions			
Random	ERROR_UNDEFINED_INSTRUCTION	0x1	Occurs if neither the processor nor any attached co-processor recognizes the currently executing instruction.
Random	ERROR_SWI	0x2	Software Interrupt is a user-defined interrupt instruction. It allows a program running in User mode, for example, to request privileged operations that run in Supervisor mode.
Random	ERROR_PREFETCH_ABORT	0x3	Occurs when the processor attempts to execute an instruction that has been prefetched from an illegal address.
Random	ERROR_DATA_ABORT	0x4	Occurs when a data transfer instruction attempts to load or store data at an illegal address.
Random	ERROR_IRQ	0x5	Occurs when the processor external interrupt request pin is asserted (LOW) and IRQ interrupts are enabled.
Random	ERROR_FIQ	0x6	Occurs when the processor external fast interrupt request pin is asserted (LOW) and FIQ interrupts are enabled.
Device Errors – I2C			
Random	ERROR_I2C_TIMEOUT	0x11	
Random	ERROR_I2C_RESTART	0x12	
Random	ERROR_I2C_NODEV	0x13	
Random	ERROR_I2C_NOT_IDLE	0x14	
Random	ERROR_I2C_NOT_BUSY	0x15	
Random	ERROR_I2C_INVALID_OFFSET	0x16	

Table continues on the next page...

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
Random	ERROR_I2C_NO_WAKEUP_INIT	0x17	
Random	ERROR_I2C_NO_WAKEUP_READ	0x18	
Random	ERROR_I2C_NOACK	0x19	
Random	ERROR_READ_TIMEOUT	0x1a	
Random	ERROR_SLAVE_ADDR_TIMEOUT	0x1b	
Random	ERROR_MEM_ADDR_TIMEOUT	0x1c	
Device Errors – ESDHC			
Random	ERROR_ESDHC_CARD_DETECT_FAIL	0x31	
Random	ERROR_ESDHC_UNUSABLE_CARD	0x32	
Random	ERROR_ESDHC_COMMUNICATION_ERROR	0x33	
Random	ERROR_ESDHC_BLOCK_LENGTH	0x34	
Device Errors – QSPI			
Random	ERROR_QSPI_INVALID_OFFSET	0x41	
Phase – "**RCW**"			
RCW Phase	ERROR_PREAMBLE	0x50	Preamble not found.
RCW Phase	ERROR_RCW_CMD_NOT_FOUND	0x51	RCW command not found
RCW Phase	ERROR_RCW_CHECKSUM_MISMATCH	0x52	Checksum mismatch in RCW
RCW Phase	ERROR_RCW_SRC_INVALID	0x58	RCW_SRC is not a valid source
RCW Phase	ERROR_RCW_REQ_NOT_SET	0x59	RCW_REQ bit never set by Reset state machine (RSM)
RCW Phase	ERROR_PBI_REQ_NOT_SET	0x60	PBI_REQ bit never set (by RSM)
Phase = **PBI**			
PBI Phase	ERROR_SEC_CAAM_INIT	0x61	CAAM init failed (Would rarely occur)
PBI Phase	ERROR_SEC_CAAM_NOT_FOUND	0x62	CAAM block not found in case of secure boot
PBI Phase	ERROR_PBI_SRC_NOT_SAME_AS_RCW_SRC	0x64	Mismatch between RCW_SRC and PBI_SRC fields
PBI Phase	ERROR_PBI_LENGTH	0x65	PBI Length defined in RCW[PBI_LEN] field is invalid
PBI Phase	ERROR_PBI_LAST _CMD_NOT_STOP	0x66	STOP or CRC&STOP not found at the end in the specified PBI Length.

Table continues on the next page...

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
PBI Phase	ERROR_PBI_ COMMAND_UNKNOWN	0x67	An invalid command parsed by PBI Parser
PBI Phase	ERROR_CAAM_SELF_TEST	0x6a	CAAM self-test failed
PBI Phase	ERROR_PBI_ COPY_INVALID_ SRC_TYPE	0x70	Copy command, src field doesn't match the RCW_SRC field
PBI Phase	ERROR_PBI_ COPY_INVALID_ DST_ADDR	0x71	Copy command, dest field isn't 0x00
PBI Phase	ERROR_PBI_ COPY_INVALID_SRC_ADDR_ SRC_ADDR	0x72	SRC Address is invalid (ROM/ OCRAM reserved for SP)
PBI Phase	ERROR_PBI_CCSR_BYTE_COUNT	0x74	Byte count in CCSR Write not valid
PBI Phase	ERROR_PBI_CCSR_4_BYTE_ALLIGN ED	0x75	Offset is not 4 byte aligned
PBI Phase	ERROR_PBI_CCSR_OFFSET_INVALID	0x76	Offset is invalid i.e less than allowed CCSR Base 0x0100_0000
PBI Phase	ERROR_PBI_ACSR_INVALID_ADDRE SS	0x78	Source address in ACSR invalid (invalid addresses - OCRAM or ROM address)
PBI Phase	ERROR_PBI_ACSR_BYTE_COUNT	0x79	Byte count in ACSR write command not valid
PBI Phase	ERROR_PBI_ACSR_WINDOW_NOT_S ET	0x7a	ATU Window is not configured
PBI Phase	ERROR_PBI_ACSR_OFFSET_ALLIGN ED	0x7b	ACSR offset is invalid and trying to write to Reserved space on OCRAM.
PBI Phase	ERROR_PBI_ALTCFG_WNDW_INVALI D	0x7c	ATU Window is invalid
PBI Phase	ERROR_PBI_JUMP_OUT_LENGTH	0x80	Offset specified in JUMP command doesn't lie in PBI length range
PBI Phase	ERROR_PBI_JUMP_4_BYTE_ALLIGNE D	0x81	Offset specified in JUMP command is not 4 byte aligned
PBI Phase	ERROR_PBI_JUMP_OFFSET_0	0x82	Offset specified in JUMP command is 0
PBI Phase	ERROR_PBI_LOADC_4_BYTE_ALLIGN ED	0x84	Address specified in LOAD Condition command is not 4 byte alligned
PBI Phase	ERROR_PBI_JUMPC_OUT_LENGTH	0x88	Offset specified in JUMP command doesn't lie in PBI length range
PBI Phase	ERROR_PBI_JUMPC_4_BYTE_ALLIGN ED	0x89	Offset specified in JUMP Conditional command is not 4 byte aligned
PBI Phase	ERROR_PBI_JUMPC_CONDITION_NO T_SET	0x8a	Jump conditional command encountered before condition is set using Load Condition

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
PBI Phase	ERROR_PBI_CRC_MISMATCH	0x90	CRC Mismatch
PBI Phase	ERROR_PBI_POLL	0x91	Poll Timeout
PBI Phase	ERROR_PBI_POLL_4_BYTE_ALLIGNED	0x92	Address being polled is not 4 byte aligned
PBI Phase	ERROR_PBI_BOOT1_CSF_INVALID_ADDR	0x94	Address of CSF Header is not valid.
PBI Phase	ERROR_PBI_BOOT1_CSF_ALLIGNED	0x95	Address of CSF Header is not 4 byte aligned
Phase = **Verify** (System State Errors (Secure boot))			
Before PBI verification	ERROR_STATE_NOT_CHECK	0xf0	SEC_MON State Machine not in CHECK state at start of ISBC in primary flow. Some Security violation could have occurred.
Before PBI verification	ERROR_STATE_NOT_CHECK_TRUSTED	0xf1	SEC_MON State Machine not in CHECK/ Trusted state at start of ISBC in secondary flow.
Phase = **Verify** (Secure Boot Fatal errors)			
Verify PBI	ERROR_PBI_COMMANDS_NOT_FOUND	0xf4	Not having PBI commands in RCW is error scenario for secure boot
Verify PBI	ERROR_SEC_HDR_NOT_FOUND	0xf5	Error if security header command not found in RCW. Expected location of Security Header command • After Preamble for hard coded RCW • After preamble and rcw for other RCW sources
Phase = **Verify** (Secure Boot Fatal (Header parsing errors))			
Verify PBI	ERROR_HEADER_LOC	0xf8	Header Location is invalid
Verify PBI	ERROR_HEADER_BARKER	0xf9	Barker code in the header is incorrect.
Verify PBI	ERROR_HEADER_INVALID	0xfa	Flag B01 in the header identifies this as SPL Header.
Phase = **Verify** (Secure Boot Non Fatal (Key/UID related errors))			
Verify PBI	ERROR_INVALID_SRK_ENTRY_KEYLEN	0x210	Length of public key specified in one of the entries in srk table is not one of the supported values. (1k, 2k or 4k)
Verify PBI	ERROR_ KEY_LEN_ NOT_TWICE_SIG_LEN	0x211	Public key is not twice the length of the RSA signature
Verify PBI	ERROR_ KEY_MOD_1	0x212	Most significant bit of modulus in header is zero.

Table continues on the next page...

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
Verify PBI	ERROR_ KEY_MOD_2	0x213	Modulus in header is even number
Verify PBI	ERROR_ SIG_KEY_MOD	0x214	Signature value is greater than modulus in header
Verify PBI	ERROR_ INVALID_SRK_NUM_ENTRY	0x215	Number of entries field in CSF Header is > 8(This is when srk_flag in header is 1)
Verify PBI	ERROR_ INVALID_KEY_NUM	0x216	Key number to be used from srk table is not present in table.(This is when srk_flag in header is 1)
Verify PBI	ERROR_ KEY_REVOKED	0x217	Key selected from srk table has been revoked(This is when srk_flag in header is 1)
Verify PBI	ERROR_ FSL_UID	0x220	FSL_UID in ESBC Header did not match the FSL_UID in SFP if fsl uid flag Is 1
Verify PBI	ERROR_ OEM_UID0	0x221	OEM_UID0 in ESBC Header did not match the OEM_UID0 in SFP if oem uid0 flag is 1.
Verify PBI	ERROR_ OEM_UID1	0x222	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify PBI	ERROR_ OEM_UID2	0x223	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify PBI	ERROR_ OEM_UID3	0x224	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify PBI	ERROR_ OEM_UID4	0x225	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Phase = **Verify** (Header Verification Failure) Secure Boot Non Fatal			
Verify PBI	ERROR_ HASH_COMPARE_KEY	0x240	Super Root Key Hash Comparison failure. Mismatch in the hash of the public key/srk table as present in the header with the value in the SRK HASH fuse.
Verify PBI	ERROR_ HASH_COMPARE_EM	0x241	RSA signature check failure. Signature provided by you in the header doesn't match with the signature of the ESBC image generated by ISBC. The ESBC image loaded by you may be different than the image used while generating the signature(using CST)
Phase = **Verify** (Secure Boot Fatal (Header parsing errors))			
Verify Boot1	ERROR_HEADER_LOC	0x100f8	Header Location is invalid
Verify Boot1	ERROR_HEADER_BARKER	0x100f9	Barker code in the header is incorrect.
Verify Boot1	ERROR_HEADER_INVALID	0x100fa	Flag B01 in the header identifies this as SPL Header.

Table continues on the next page...

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
Phase = Verify (Secure Boot Fatal (SG Table related errors))			
Verify Boot1	ERROR_SG_ENTRY_POINT	0x10200	Entry point is not within any of SG Entries
Verify Boot1	ERROR_SG_NUM_ENTRY	0x10201	No. of entries in SG Table is 0 or >8
Verify Boot1	ERROR_SG_SIZE_ZERO	0x10202	A SG entry has size 0
Phase = **Verify** (Secure Boot Non-Fatal (Key/UID related errors))			
Verify Boot1	ERROR_INVALID_SRK_ENTRY_KEYLEN	0x10210	Length of public key specified in one of the entries in srk table is not one of the supported values. (1k, 2k or 4k)
Verify Boot1	ERROR_ KEY_LEN_ NOT_TWICE_SIG_LEN	0x10211	Public key is not twice the length of the RSA signature
Verify Boot1	ERROR_ KEY_MOD_1	0x10212	Most significant bit of modulus in header is zero.
Verify Boot1	ERROR_ KEY_MOD_2	0x10213	Modulus in header is even number
Verify Boot1	ERROR_ SIG_KEY_MOD	0x10214	Signature value is greater than modulus in header
Verify Boot1	ERROR_ INVALID_SRK_NUM_ENTRY	0x10215	Number of entries field in CSF Header is > 8(This is when srk_flag in header is 1)
Verify Boot1	ERROR_ INVALID_KEY_NUM	0x10216	Key number to be used from srk table is not present in table.(This is when srk_flag in header is 1)
Verify Boot1	ERROR_ KEY_REVOKED	0x10217	Key selected from srk table has been revoked(This is when srk_flag in header is 1)
Verify Boot1	ERROR_ FSL_UID	0x10220	FSL_UID in ESBC Header did not match the FSL_UID in SFP if fsl uid flag Is 1
Verify Boot1	ERROR_ OEM_UID0	0x10221	OEM_UID0 in ESBC Header did not match the OEM_UID0 in SFP if oem uid0 flag is 1.
Verify Boot1	ERROR_ OEM_UID1	0x10222	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify Boot1	ERROR_ OEM_UID2	0x10223	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify Boot1	ERROR_ OEM_UID3	0x10224	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Verify Boot1	ERROR_ OEM_UID4	0x10225	OEM_UID1 in ESBC Header did not match the OEM_UID1 in SFP if oem uid1 flag is 1.
Phase = **Verify** (Header Verification Failure) Secure Boot Non-Fatal			

Table continues on the next page...

Table 387. ISBC Error Codes (continued)

When Error Generated	Error Code	Value	Description
Verify Boot1	ERROR_ HASH_COMPARE_KEY	0x10240	Super Root Key Hash Comparison failure. Mismatch in the hash of the public key/srk table as present in the header with the value in the SRK HASH fuse.
Verify Boot1	ERROR_ HASH_COMPARE_EM	0x10241	RSA signature check failure. Signature provided by you in the header doesn't match with the signature of the ESBC image generated by ISBC. The ESBC image loaded by you may be different than the image used while generating the signature(using CST)
Verify Boot1	ERROR_PRIVATE_KEY_DERIVATION	0x10250	Error in Private key derivation when enabling Manufacturing Protection.

10.3.3.11 ESBC Error Codes

Table 388. ESBC Validation Failures

Value	Code	Definition
0x4	ERROR_ESBC_CLIENT_HEADER_BARKER	Wrong barker code in header
0x8	ERROR_ESBC_CLIENT_HEADER_KEY_LEN	Wrong public key length in header
0x10	ERROR_ESBC_CLIENT_HEADER_SIG_LEN	Wrong signature length in header
0x20	ERROR_ESBC_CLIENT_HEADER_KEY_LEN_NOT_TWICE_SIG_LEN	Public key length not twice of signature length
0x40	ERROR_ESBC_CLIENT_HEADER_KEY_MOD_1	Public key Modulus most significant bit not set
0x80	ERROR_ESBC_CLIENT_HEADER_KEY_MOD_2	Public key Modulus in header not odd
0x100	ERROR_ESBC_CLIENT_HEADER_SIG_KEY_MOD	Signature not less than modulus
0x400	ERROR_ESBC_CLIENT_HASH_COMPARE_KEY	Public key hash comparison failed
0x800	ERROR_ESBC_CLIENT_HASH_COMPARE_EM	RSA verification failed

Table continues on the next page...

Table 388. ESBC Validation Failures (continued)

Value	Code	Definition
0x10000	ERROR_ESBC_CLIENT_HEADER_SG	No SG support
0x20000	ERROR_ESBC_WRONG_CMD	Failure in command/Unknown command/Wrong arguments of boot script.
0x40000	ERROR_ESBC_MISSING_BOOTM	Bootm command missing from boot script.

10.3.3.12 Address Map used for demo

The Base addresses for device/flash are:

NOR (Bank 0) 0x5_8000_0000 (0x3000_0000[42])

NOR (Alt Bank 4) 0x5_8400_0000 (0x3400_0000)

Table 389. Address Map Used For Demo

Offset on Flash/Device	Address on DDR (To Copy the Image)	Size (Reserved)	Definition
0x0	<>	0x10_0000 (1 MB)	rcw_sec.bin
0x010_0000	<>	0x10_0000 (1 MB)	Boot Loader (U-Boot.bin)
0x020_0000	<>	0x10_0000 (1 MB)	Boot Loader Environment
0x030_0000	<>	0x40_0000 (4 MB)	MC FW
0x070_0000	0xA070_0000	0x10_0000 (1 MB)	MC DPL
0x080_0000	<>	0x10_0000 (1 MB)	MC DPC
0x0A0_0000	<>	0x10_0000 (1 MB)	PPA
0x0C0_0000	<>	0x4000(16K)	hdr_uboot.out
0x0C4_0000	0xA0C4_0000	0x4000 (16K)	hdr_ppa.out
0x0C8_0000	0xA0C8_0000	0x4000(16K)	hdr_mc.out
0x0CC_0000	0xA0CC_0000	0x4000(16K)	hdr_dpc.out
0x0D0_0000	0xA0D0_0000	0x4000(16K)	hdr_bs.out
0x0D4_0000	0xA0D4_0000	0x4000 (16K)	hdr_dpl.out
0x0D8_0000	0xA0D8_0000	0x4000 (16 K)	hdr_kernel.out
0x0E0_0000	0xA0E0_0000	0x2_0000 (128 KB)	BootScript
0x110_0000	0xA110_0000	0x280_0000 (40 MB)	Kernel Fit Image

[42] There is an address in 32 bit address space and 64 bit address space. Please refer the Platform Address map for details.

10.3.3.13 Useful Commands

This section contains some useful commands for loading images via U-Boot (As per memory map defined in this document) and CCS commands to load the SRK Hash in shadow registers and get the system out of Reset Pause State in Development Mode.

NOTE

The CCS commands to connect and configure config chain might change with Board/ Silicon revision. See the Board Manual/ CCS Guide in case of issues with CCS commands.The commands provided below are for reference only.

NOTE

For permanently blowing the values (OTPMK, SRK HASH etc.) in SFP, refer to the details in *Trust Architecture User Guide*. A brief summary of the steps is described below:

1. Ensure that PROG_SFP/POVDD(Table 381. Trust Architecture and SFP Information on page 2096) signal is correctly asserted. This is usually controlled via a switch or a jumper. (Refer Board schematic/manual for the same)
2. Write the required fuse values to the SFP mirror registers.
3. To permamnetly blow the fuses, write to 'PROGFB' in SFP Instruction Register (SFP_INGR).

   Make sure that the values written in SFP mirror registers are correct before blowing the fuses as once blown, the fuse values cannot be changed.

   - To check if OTPMK is blown or not on the Silicon, check the bit 'OTPMK_ZERO' in the SECMON_HPSR register. If the bit is set, it means OTPMK is zero i.e. OTPMK needs to be blown.
   - The OTPMK value can be generated using 'gen_otpmk_drbg' tool provided in CST.
   - After writing the values in SFP mirror registers, check the hamming error register. Ensure that the value is 0x0 i.e. no error is reported.(Table 381. Trust Architecture and SFP Information on page 2096)
     - It is reported in SFP Secret Value Hamming Error Status Register (SFP_SVHESR).

U-Boot Commands to Flash Images on NOR Bank 4

```
setenv dir <tftp folder path>

setenv cprcw 'protect off all ; tftp 0x80000000 $dir/rcw_sec.bin; echo Copying rcw ; erase

Enabling Reset Pause State[43]

LS2 QDS Board	Switch: **SW2.7 – 0**
	U-Boot Command: **i2c mw 0x66 0x66 0x7f 1**
LS2 RDB Board	Switch (Rev B): **SW3.8 – 0**
	Switch (Rev C to Rev E): **SW4.8 – 0**
	U-Boot Command: None (**No register available in FPGA**)
	To boot from vbank4 change **SW9[3:5] to 100**

CCS Commands to Write SRK Hash and Get System Out of Reset Pause State

```
(RSP has two states : RSP1 and RSP2. Initially we are in RSP1 state)
delete all;config cc cwtap;show cc
# use config cc cwtap:<tap_id> if using remote board
ccs::config_chain {<platform> sap2}
#display ccs::get_config_chain
puts "Entering RSP2: "
ccs::write_mem <SAP CHAIN_POS> 0x7 0x001000D0 0x4 0x0 0x800
```

[43] Please refer the board schematic/guide for exact switches on the board.

```
#Write Key In sfp  (Reversed byte order of key hash)
#Example Key Hash: c9f90c9762e1693804421a4bd8193735b38ea03b83303d9529f7b1b5d2e4688f
# Key Hash must be written after byte swapping as SRKH is Little Endian
ccs::write_mem <SAP CHAIN_POS> 0x1E80254 4 0 0x970CF9C9;
ccs::write_mem <SAP CHAIN_POS> 0x1E80258 4 0 0x3869E162;
ccs::write_mem <SAP CHAIN_POS> 0x1E8025c 4 0 0x4B1A4204;
ccs::write_mem <SAP CHAIN_POS> 0x1E80260 4 0 0x353719D8;
ccs::write_mem <SAP CHAIN_POS> 0x1E80264 4 0 0x3BA08EB3;
ccs::write_mem <SAP CHAIN_POS> 0x1E80268 4 0 0x953D3083;

ccs::write_mem <SAP CHAIN_POS> 0x1E80270 4 0 0x8F68E4D2;

puts "Exiting RSP: "
ccs::write_mem 2 0x7 0x001000D0 0x4 0x0 0x400;
```

10.3.3.14 Troubleshooting

	Symptoms	Reasons and/or Recommended actions
1.	No print on UART console.	Check the status register of sec mon block. Refer to the details of the register from the Reference Manual. Bits OTPMK_ZERO, OTMPK_SYNDROME and PE should be 0 otherwise there is some error in the OTPMK fuse blown by you. If OTMPK fuse is correct (see Step 1), check the DCFG SCRATCHRW3 register for error code. For a list of error codes see ISBC Error Codes on page 2104 If **Error code = 0** then check the Security Monitor state in HPSR register of Sec Mon. Sec Mon in Check State (0x9) If ITS fuse = 1, then it means ISBC code has reset the board. This may be due to the following reasons “ Hash of the public key used to sign the ESBC u-boot doesn’t match with the value in SRK Hash Fuse Or Signature verification of the image failed Sec Mon in Trusted State (0xd) or Non Secure State (0xb) Check the entry point field in the CSF header. If entry point is correct, ensure that u-boot image has been signed with the correct input file.
2.	Instead of linux prompt, you get a u-boot command prompt.	You have not booted in secure boot mode. You never get a u-boot prompt in secure boot flow. You would reach this stage if ITS = 0 and you are running normal uboot.
3	u-boot hangs or board resets	Some validation failure occurred in u-boot. Error code and description would be printed on u-boot console. See ESBC Error Codes on page 2111for more details on errors.

10.3.4 Code Signing Tool

To assist with signing of various images and creation of CSF header, NXP offers a Code Signing Tool (CST). It is generally expected that the CST signs images in an offline process

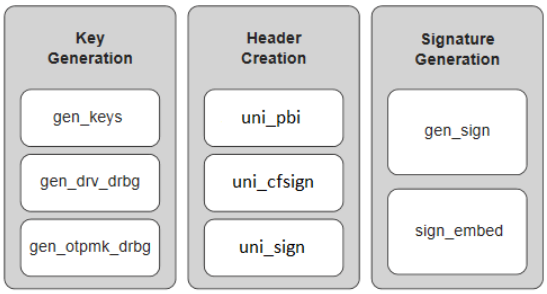

Figure 341. Tool in CST Package

CST tool installation steps

Step 1 Yocto installs the cst package at the following location:

tmp/sysroots/x86_64-linux/usr/bin/cst

OR

In the Yocto environment, the user can use below commands to rebuild cst:

1. bitbake cst-native –c cleanall
2. bitbake cst-native

Step 2 cd ***tmp/sysroots/x86_64-linux/usr/bin/cst***

Note: LD_LIBRARY_PATH should be set to the library path in yocto workspace. <project_folder_path>/tmp/sysroots/x86_64-linux/usr/lib

10.3.4.1 Key generation

The CST begins by generating a RSA public and private key pair using OPENSSL APIs. The key pair consists of 3 parts - N, E and D.

N - Modulus

E - Encryption exponent

D - Decryption exponent

Public Key - It is a combination of E and N components.

Private Key - It is a combination of D and N components.

The application allows the user to feed 3 key sizes for generating keys. The sizes allowed are - 1024 bits, 2048 bits and 4096 bits.

It is the OEM's responsibility to tightly control access to the RSA private signature key. If this key is ever exposed, attackers will be able to generate alternate images that will pass secure boot. If this key is ever lost, the OEM will be unable to update the image

10.3.4.1.1 gen_keys

This utility generates a RSA public and private key pair using OPENSSL APIs. The key pair consists of 3 parts: N, E and D.

N – Modulus

E – Encryption exponent

D – Decryption exponent

Public Key - It is a combination of E and N components.

Private Key - It is a combination of D and N components.

It is the OEM's responsibility to tightly control access to the RSA private signature key. If this key is ever exposed, attackers will be able to generate alternate images that will pass secure boot. If this key is ever lost, the OEM will be unable to update the image.

Features

- The application allows the user to generate 3 sizes keys. The sizes allowed are - 1024 bits, 2048 bits and 4096 bits.
- It generates RSA key pairs in PEM format.
- Keys are generated and stored in the files. User can provide filenames through command line option.

Usage

./gen_keys [OPTION] SIZE

SIZE refers to size of public key in bits. (Modulus size).

Sizes supported -- 1024, 2048, 4096. The generated keys would be in PEM format.

Options:

-h,--help Usage of the command

-k,--pubkey File where Public key would be stored in PEM format(default = srk.pub)

-p,--privkey File where Private key would be stored in PEM format(default = srk.priv)

Usage Example

```
$ ./gen_keys 1024

    #------------------------------------------------------#

10.3.4.1.2 gen_otpmk_drbg

This utility in the Code Signing Tool inserts hamming code in a user defined 256b hexadecimal string, or generate a 256b hexadecimal random number and inserts the hamming code in it which can be used as OTPMK value.

NOTE

For random number generation, Hash_DRBG library is used. The Hash_DRBG is an implementation of the NIST approved DRBG(Deterministic Random Bit Generator), specified in SP800-90A. The entropy source is the Linux /dev/random.

Features:

- Generates random numbers, which can be used if user defined string is not provided, to generate OTPMK value.
- Calculates and embeds the hamming code in the hexadecimal string.

Usage:

./gen_otpmk_drbg <bit_order> [string]

<bit_order> : (1 or 2) OTPMK Bit Ordering Scheme in SFP

1 : BSC913x, P1010, P3, P4, P5, C29x

2 : T1, T2, T4, B4, LSx

<string> : 32 byte string

In case string is not specified, the utility generates a 32 bytes random number and embeds hamming code in it.

Usage Example:

```
$ ./gen_otpmk_drbg 2

    #--------------------------------------------------#
    #-------         --------     --------        -------#
```

```
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #------------------------------------------------------#

10.3.4.1.3 gen_drv_drbg

This utility in the Code Signing Tool inserts hamming code in a user defined 64b hexadecimal string, or generate a 64b hexadecimal random number and inserts the hamming code in it which can be used as Debug Response Value.

NOTE

For random number generation, Hash_DRBG library is used. The Hash_DRBG is an implementation of the NIST approved DRBG(Deterministic Random Bit Generator), specified in SP800-90A. The entropy source is the Linux /dev/random.

Features:

- Generates random numbers, which can be used if user defined string is not provided, to generate Debug Response value.
- Calculates and embeds the hamming code in the hexadecimal string.

Usage:

./gen_drv_drbg <Hamming_algo> [string]

Hamming_algo : Platforms

A1 : T10xx, T20xx, T4xxx, P4080rev1, B4xxx

A2 : LSx

B : P10xx, P20xx, P30xx, P4080rev2, P4080rev3, P50xx, BSC913x, C29x

string : 8 byte string

In case string is not specified, the utility generates an 8 byte random number and embeds hamming code in it.

Usage Example:

```
$ ./gen_drv_drbg A2

    #-------------------------------------------------#
    #-------         --------     --------        -------#
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #-------------------------------------------------#

Input string not provided

```

10.3.4.2 Header creation

10.3.4.2.1 uni_pbi

Options available with the uni_pbi command are as follows:

```
$ ./uni_pbi
        --verbose    Display header Info after Creation. This option is invalid for TA2 platform
        --hash       Print the SRK(Public key) hash. This option is invalid for TA2 platform
        --img_hash   Header is generated without Signature.
                     Image Hash is stored in a separate file. This option is invalid for TA2
platform
        --help       Show the Help for Tool Usage.
```

The input to this tool will be an input file specifying the platform, and based on that there are two separate behaviour of the tool:

uni_pbi for TA2.x platforms is used for the following:

- To add boot location pointer and set SB_EN and BOOT_HO value for secure boot
- (optional) To add PBI commands (ACS write commands to add u-boot-spl and its header to OCRAM from Non-XIP memory).
- (optional) To append images (uboot, bootscript and their headers) to RCW file.

Refer Hardware PreBoot Loader (PBL) Based Platforms on page 1940 for TA2.x based platforms

uni_pbi for Service processor based platforms

- uni_pbi tool is used for creating signature and header over PBI commands.

Table 390. Description of Fields in input files of both type of platforms (TA2.x and TA3.x)

Field Name	Description	Platform supported
PLATFORM	The platform for which tool is being used	TA 2.x and TA 3.x
RCW_PBI_FILENAME	Input image file name. The rcw file which has to be modified.	TA 2.x and TA 3.x
BOOT1_PTR	Address of ISBC (Boot1) CSF Header	TA 2.x and TA 3.x
OUTPUT_RCW_PBI_FILENAME	To identify the platform for which the tool is being used.. This field is optional. if not specified, it will take default name.	TA 2.x
BOOT_SRC	Only to be specified in case of **SD boot**	TA 2.x
SB_EN	Field to enable/disable secure boot, by setting SB_EN bit in rcw file to 1	TA 2.x
BOOT_HO	To put core in hold-off state to fuse key hash in case of secure boot, by settin BOOT_HO bit in rcw file to 1	TA 2.x
COPY_CMD	To add ACS write commands to write u-boot spl and is header to OCRAM. This is an optional field. If not mentioned, won't add the command.	TA 2.x
APPEND_IMAGES	To append u-boot, bootscript and their headers to the new rcw generated. It is an optional field. This is an optional field, if not specified no images will be appended.	TA 2.x

Table continues on the next page...

Table 390. Description of Fields in input files of both type of platforms (TA2.x and TA3.x) (continued)

Field Name	Description	Platform supported
KEY_SELECT	Specify the key to be used in signature generation from the SRK Table	TA 3.x
PRI_KEY	Private key filename in PEM format. Maximum 8 keys supported.	TA 3.x
FSL_UID_x	FSL UID(s) to be populated in the header	TA 3.x
OEM_UID_x	OEM UID(s) to be populated in the header	TA 3.x
OUTPUT_HDR_FILENAME	Output File name of the Header. An out put file name is generated with rcw commands appended with signed PBI commands.	TA 3.x
IMAGE_HASH_FILENAME	used with '--img_hash' option (Name of file in which Image Hash is stored)	TA 3.x
MP_FLAG	Manufacturing Protection Flag	TA 3.x
ISS_FLAG	Increment Security State Flag	TA 3.x
LW_FLAG	Leave Writeable Flag	TA 3.x
VERBOSE	Specify VERBOSE as 1, if you want to Display Header Information. Can also be done with '--verbose' option	TA 3.x
IE_TABLE_ADDR	64 bit address of IE table(to be used in case of IE key extension feature usage)	TA 3.x

Sample input files are present in the CST tool at location: input_files/uni_pbi/<platform>/

eg. input_files/uni_pbi/ls1/input_pbi_sd_secure

NOTE

In TA 3.x, SB_EN and BOOT_HO fields are by default set to 1 to enable secure boot.

NOTE

TA 3.x : LS1088, LS2088. To know platforms under TA 2.x refer Trust Architecture and SFP Information on page 1996

10.3.4.2.1.1 Sample Input File

Sample input file for TA2 based platforms

```
/*
 * Copyright 2016 NXP
 */
------------------------------------------------------------------------------
# For PBI Creation
# Name of RCW + PBI file [Mandatory]
RCW_PBI_FILENAME= u-boot-with-spl-pbl.bin
------------------------------------------------------------------------------
# Specify the output file name [Optional].
# Default Values chosen in Tool
OUTPUT_RCW_PBI_FILENAME=u-boot-with-spl-pbl-sec.bin
------------------------------------------------------------------------------
```

```
#specify the boot src
BOOT_SRC=SD_BOOT
# Specify the platform
PLATFORM=LS1020
# Specify the RCW Fields. (0 or 1) - [Optional]
SB_EN=1
BOOT_HO=1
BOOT1_PTR=10016000
--------------------------------------------------------------------------------
# Specify the PBI commands - [Optional]
# Argument: COPY_CMD = (src_offset, dest_offset, Image name)
# Split hdr_uboot_spl.out in PBI commads
COPY_CMD={ffffffff,10016000,hdr_uboot_spl.out;}
--------------------------------------------------------------------------------
# Specify the Images to be appended
# Arguments: APPEND_IMAGES=(Image name, Offset from start)
APPEND_IMAGES={u-boot-dtb.bin,00022000;}
APPEND_IMAGES={hdr_uboot.out,00122000;}
APPEND_IMAGES={hdr_bs.out, 00124000;}
APPEND_IMAGES={bootscript,00128000;}
--------------------------------------------------------------------------------
```

Sample input file for SP based platforms

```
--------------------------------------------------
# Specify the platform. [Mandatory]
# Choose Platform -
# TRUST 3.1: LS2088, LS1088
PLATFORM=LS1088
--------------------------------------------------
# Specify the Key Information.
# PUB_KEY [Mandatory] Comma Seperated List
# Usage: <srk1.pub>, <srk2.pub> .....
PUB_KEY=srk.pub
# KEY_SELECT [Mandatory]
# USAGE (for TRUST 3.1): (between 1 to 8)
KEY_SELECT=1
# PRI_KEY [Mandatory] Comma Seperated List for Signing
# USAGE: <srk.pri>, <srk2.pri>
PRI_KEY=srk.pri
--------------------------------------------------
# For PBI Signing
# Name of RCW + PBI file [Mandatory]
RCW_PBI_FILENAME=rcw.bin
# Address of ISBC (Boot1) CSF Header [Mandatory]
BOOT1_PTR=20c00000
--------------------------------------------------
# Specify OEM AND FSL ID to be populated in header. [Optional]
# e.g FSL_UID_0=11111111
FSL_UID_0=
FSL_UID_1=
OEM_UID_0=
OEM_UID_1=
OEM_UID_2=
OEM_UID_3=
OEM_UID_4=
--------------------------------------------------
# Specify the output file names [Optional].
# Default Values chosen in Tool
```

```
OUTPUT_HDR_FILENAME=rcw_sec.bin
IMAGE_HASH_FILENAME=
-------------------------------------------------
# Specify The Flags. (0 or 1) - [Optional]
MP_FLAG=0
ISS_FLAG=1
LW_FLAG=0
-------------------------------------------------
# Specify VERBOSE as 1, if you want to Display Header Information [Optional]
VERBOSE=0
```

10.3.4.2.2 CF Header Generation

uni_cfsign command is provided to generate cf header.

./uni_cfsign INPUT_FILE

A QORIQ device can boot securely from multiple targets like NOR flash, NAND flash , SPI flash and SD/MMC (P1010 does not support SD/MMC). For each target, an input file is built which contains the configuration words and populates the S/G table. CF header is generated with the information as described in CF Header Data Structure Definition on page 2041. Legacy mode fields contain the information related to the legacy image like source address, destination address, length and entry point. Configuration words are used to – create LAW for DDR, initialize the DDR controller. ESBC source address points to the ESBC/CSF header. CF header generation is valid only for the below mentioned platforms

- p1010
- bsc9131
- bsc9132
- c290

INPUT_FILE - Sample input files have been provided in the input_files directory in the cst tool.

- input_files/uni_cfsign/p1010/
- input_files/uni_cfsign/bsc9131/
- input_files/uni_cfsign/bsc9132/
- input_files/uni_cfsign/c290/

For cf header generation input file contains following major piece of information -

1. Target interface ID (IMAGE_TARGET)
2. Address where ESBC header will placed on the target (ESBC_HDRADDR)
3. Configuration words (address/data tuples)

The use of configuration address and data pairs for the following configuration is not allowed before the control is given to the ESBC image:

- Change of CCSRBAR
- Programming of ALTCSR
- Programming of boot page translation register
- SNVS
- CCSR Access Control
- Secure Debug Control
- MPIC
- SFP

There are certain points which should be adhered to while writing the configuration file:

1. The CF Header should be on the boot_device within first 512bytes.
2. If using the same data structure for secure and non secure booting modes, make sure that entry points are different in both cases.
3. In legacy mode with SD/MMC card in high capacity mode, the Source Address field is translated as containing the address in block address format. Whereas, in case of Secure mode even if the SD/MMC card is High capacity the public key offset, signature offsets are all treated as 32 bit values. For all the other interfaces all address fields are read as 32bit values.
4. If the cfg_rom_loc is SD/MMC, the IBR SD/MMC driver code will throw an error if the address is not aligned. For instance, the Source address must be aligned, and in case an address is constructed with the summation of base and offset the resultant address must be aligned. The alignment value is 0x200. i.e the address should be 512 byte aligned. The alignment requirement is only for SD/MMC.

Sample input file to generate CF Header is as follows –

```
--------------------------------------------------
# Specify the platform. [Mandatory]
# Choose Platform - 1010/9131/9132/1040/C290
PLATFORM=C290
--------------------------------------------------
# Primary Image Header Address - [Mandatory]
ESBC_HDRADDR=CC002000
--------------------------------------------------
# Specify the file name of the keys seperated by comma.
# The number of files and key select should lie between 1 and 4 for 1040 and C290.
# For rest of the platforms only one key is required and key select should not be provided.

# USAGE (for 1010/913x): PRI_KEY = key1.pri
# USAGE (for 1040/C290): PRI_KEY = key1.pri, key2.pri, key3.pri, key4.pri

# PRI_KEY (Default private key :srk.pri) - [Optional]
PRI_KEY=srk.pri
# Please provide KEY_SELECT(between 1 to 4) (Required for 1040 and C290 only) - [Optional]
KEY_SELECT=
--------------------------------------------------
# Specify the target where image will be loaded. - [Mandatory]
# Select from - NOR_8B/NOR_16B/NAND_8B_512/NAND_8B_2K/NAND_8B_4K/NAND_16B_512/NAND_16B_2K/
NAND_16B_4K/SD/MMC/SPI
IMAGE_TARGET= NAND_8B_512
--------------------------------------------------
# Specify Configuration Words (Address Data Pairs), Max 1024 such pairs are supported.
# USAGE : CF_WORD = {ADDR, DATA}
CF_WORD=(0xff700d28 , 0x000ca000)
CF_WORD=(0xff700d30 , 0x80a00012)

--------------------------------------------------
# Specify the file names of cf header. (Default : cf_hdr.out) - [Optional]
OUTPUT_HDR_FILENAME=cf_hdr.out
--------------------------------------------------
# Primary Image Header Address (Required for C290 and 1040 only) - [Mandatory]
ESBC_HDRADDR_SEC_IMAGE=CFFFFFFC
-----------------------
```

NOTE

The right input file is picked as per the specified interface/platform and user can change the fields based on the requirement.

10.3.4.2.3 uni_sign

uni_sign tool can be used for the following functions :

- CSF header generation along with signature for both ISBC and ESBC phase
- CSF header generation without signature if private key is not provided

  uni_sign tool (with ESBC = 0 in input file) is used for creating signature and header over Boot1 image to be verified by ISBC

  uni_sign tool (with ESBC = 1 in input file) is used for creating signature and header over images to be verified by ESBC.

Options available with the uni_sign command are as follows:

Usage:

To view usage of tool:

```
./uni_sign
    --verbose    Display header Info after Creation
    --hash       Print the SRK(Public key) hash.
    --img_hash   Header is generated without Signature.
                 Image Hash is stored in a separate file.
    --help       Show the Help for Tool Usage.
```

Table 391. Description of Fields

Field	Field Description	Platform supported
PLATFORM	To identify the platform/SoC for which CF Header needs to be created.	All
ESBC	Don't set this flag when code signing is being performed on the image directly verified by the ISBC. For later images in the chain of trust, set this flag.	TA3.x
ENTRY_POINT	Entry Point address / Image start address field in the header.	All
PRI_KEY	Private key filename to be used for signing the image. (File has to be in PEM format) (default = srk.pri generated by gen_keys command) FILE1 [,FILE2, FILE3, FILE4]. Multiple key support for Trust Arch v2.x devices only.	All
PUB_KEY	Public key filename in PEM format. (default = srk.pub generated by gen_keys) FILE1 [,FILE2, FILE3, FILE4]. Multiple key support for Trust Arch v2.x devices only.	All
KEY_SELECT	Specify the key to be used in signature generation when more than one key has been given as input. (Default=1, first key will be selected)	All
IMAGE_1 - IMAGE_8	Create Entries for SG Table in the format { IMAGE_NAME, SRC_ADDR, DST_ADDR }	All
OEM_UID_x	OEM UID to be populated in the header.	All
FSL_UID_x	FSL UID to be populated in header.	All
HK_AREA_POINTER	House Keeping Area Starting Pointer Required by Sec (Required for Trust Arch v2.x devices only when esbc option is not provided)	TA2.x

Table continues on the next page...

Table 391. Description of Fields (continued)

Field	Field Description	Platform supported
HKAREA_SIZE	House Keeping Area Size (Required for Trust Arch v2.x devices only when esbc option is not provided)	TA2.x
OUTPUT_HDR_FILENAME	Name of the combined header binary to be created by tool	All
SG_TABLE_ADDR	Specify SG_TABLE Address where Scatter Gather table is present for 2041/3041/4080/5020/5040 when ESBC=0.	TA1.x
OUTPUT_SG_BIN	Specify the output file name of sg table.	TA1.x
IMAGE_TARGET	Specify the target where image will be loaded. Ex:NOR_8B/NOR_16B/ NAND_8B_512/NAND_8B_2K/NAND_8B_4K/ NAND_16B_512/ NAND_16B_2K/NAND_16B_4K/SD/MMC/SPI	All
SEC_IMG	Flag for Secondary Image. Required for Trust Arch v2.x devices only	TA2.x
MP_FLAG	Specify Manufacturing Protection Flag. Available for LS1 only.	All, only needed in ISBC phase
VERBOSE	Specify Verbose option. Contents of header generated will be printed.	All
IMAGE_HASH_FILENAME	used with '--img_hash' option (Name of file in which Image Hash is stored)	TA3.x
ISS_FLAG	Increment Security State Flag	TA3.x, only needed in ISBC phase
LW_FLAG	Leave Writeable Flag	TA3.x, only needed in ISBC phase
ESBC_HDRADDR	32 bit address where header generated shall be placed. Used to calculate IE key table address	TA3.x, only to be used in case of IE key extension feature usage
IE_KEY	comma separated list of files containing public keys(IE Keys)	TA3.x, only to be used in case of IE key extension feature usage
IE_REVOC	Comma seperated list of numbers that are to be revoked from IE Table	TA3.x, only to be used in case of IE key extension feature usage
IE_KEY_SEL	No of keys in IE table that is to be used to validate image	TA3.x, only to be used in case of IE key extension feature usage

Sample input files can be referred to, from input_files/uni_sign/I<platform>

For IE keys u can refer to input_files/uni_sign/l<platform>/ie_ke

TA3.x: LS2088 and LS1088. To know platforms under TA1.x and TA 2.x refer Trust Architecture and SFP Information on page 1996

10.3.4.2.3.1 Sample Input File

The input files will not have ESBC field (ESBC=0).

```
--------------------------------------------------
# Specify the platform. [Mandatory]
# Choose Platform -
# TRUST 3.1: LS2088, LS1088
# TRUST 1.0, 1.1, 2.0, 2.1: 1010/1040/2041/3041/4080/5020/5040/9131/9132/9164/4240/C290/LS1
PLATFORM=LS2088
--------------------------------------------------
# Entry Point/Image start address field in the header.[Mandatory]
# (default=ADDRESS of first file specified in images)
# Address can be 64 bit
ENTRY_POINT=30008000
--------------------------------------------------
# Specify the Key Information.
# PUB_KEY [Mandatory] Comma Seperated List
# Usage: <srk1.pub> <srk2.pub> .....
PUB_KEY=srk.pub
# KEY_SELECT [Mandatory]
# USAGE (for TRUST 3.1): (between 1 to 8)
KEY_SELECT=1
# PRI_KEY [Mandatory] Comma Seperated List for Signing
# USAGE: <srk.pri>, <srk2.pri>
PRI_KEY=srk.pri
--------------------------------------------------
# Specify IMAGE, Max 8 images are possible.
# DST_ADDR is required only for Non-PBL Platform. [Mandatory]
# USAGE : IMAGE_NO = {IMAGE_NAME, SRC_ADDR, DST_ADDR}
# Address can be 64 bit
IMAGE_1={u-boot.bin,30008000,ffffffff}
IMAGE_2={,,}
IMAGE_3={,,}
IMAGE_4={,,}
IMAGE_5={,,}
IMAGE_6={,,}
IMAGE_7={,,}
IMAGE_8={,,}
--------------------------------------------------
# Specify OEM AND FSL ID to be populated in header. [Optional]
# e.g FSL_UID_0=11111111
FSL_UID_0=
FSL_UID_1=
OEM_UID_0=
OEM_UID_1=
OEM_UID_2=
OEM_UID_3=
OEM_UID_4=
--------------------------------------------------
# Specify the output file names [Optional].
# Default Values chosen in Tool
OUTPUT_HDR_FILENAME=hdr_uboot.out
IMAGE_HASH_FILENAME=
```

```
RSA_SIGN_FILENAME=

------------------------------------------------
# Specify The Flags. (0 or 1) - [Optional]
MP_FLAG=0
ISS_FLAG=1
LW_FLAG=0

------------------------------------------------
# Specify VERBOSE as 1, if you want to Display Header Information [Optional]
VERBOSE=0
------------------------------------------------
# Following fields are Required for 4240/9164/1040/C290 only

# Specify House keeping Area
# Required for 42409164/1040/C290 only when ESBC flag is not set. [Mandatory]
HK_AREA_POINTER=
HK_AREA_SIZE=
------------------------------------------------
# Following field Required for 4240/9164/1040/C290 only
# Specify Secondary Image Flag. (0 or 1) - [Optional]
# (Default is 0)
SEC_IMAGE=
------------------------------------------------
# Specify SG table address, only for (2041/3041/4080/5020/5040) with ESBC=0 - [Optional]
SG_TABLE_ADDR=
```

10.3.4.3 Signature generation

The tools in this category are provided in case the user does not want to share the Private Key with the CST Tool. The **--img_hash** option in Header creation on page 2121 Tools provides OEMs with the ability to perform code signing in a secure environment which does not run the NXP Code Signing Tool.

--img_hash option

- Generates hash file in binary format which contains SHA256 hash of the componenets required for signature.
- Generates output header binary file based on the fields specified in input file.
- Output header binary file doesn't contain signature.
- Provides flexibility to manually append signature at the end of output header file. User's can use their own custom tool to generate the signature. The signature offset chosen in the header is such that the signature can be appended at the end of the header file.
- This option does not require private key to be provided. But the corresponding Public key from the public/ private key pair must be provided to calculate correct SHA256 hash.
- The SHA256 hash generated over CF Header (in case of TA1.x platforms)) is then signed using RSA algorithm (OPENSSL APIs) with the private key . This encrypted hash is known as digital signature. This signature is placed at an offset from the CF header, which is later read by IBR.
- The SHA256 hash generated over CSF header, the Public Key, the S/G Table and the ESBC is also signed using RSA algorithm with the same private key . The signature generated is placed at an offset from the CSF header, which is again later read by IBR.

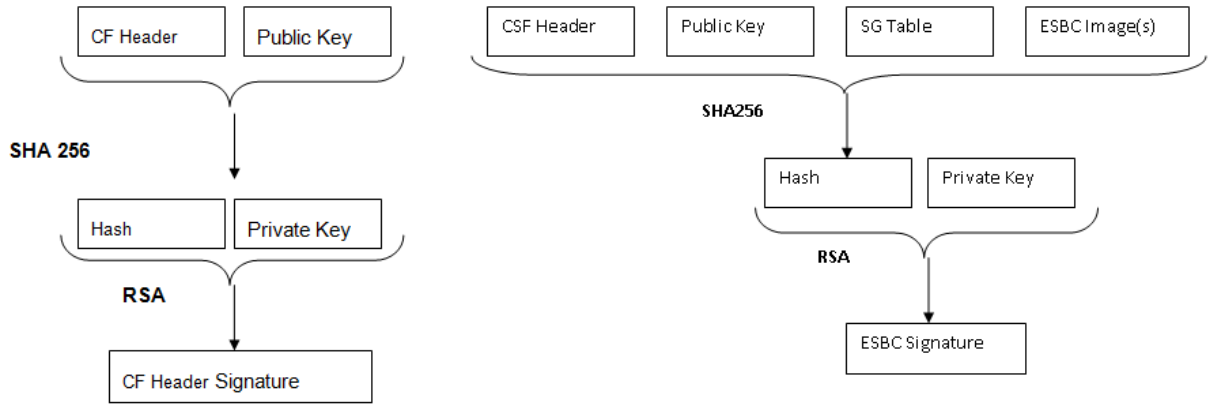

Figure 342. Dual signature generation

Usage Example

```
$ ./uni_sign --img_hash --verbose input_files/uni_sign/<platform>/input_uboot_nor_secure

    #-------------------------------------------------------#
    #-------         --------     --------        -------#
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #-------------------------------------------------------#

============================================================
This tool includes software developed by OpenSSL Project
for use in the OpenSSL Toolkit (http://www.openssl.org/)
This product includes cryptographic software written by
Eric Young (eay@cryptsoft.com)
============================================================

Input File is input_files/uni_sign/<platform>/input_uboot_nor_secure

***********************************************
* Image Hash Stored in File: hash.out
* Header File is w/o Signature appended
***********************************************

Header File Created: hdr_uboot.out

SRK (Public Key) Hash:
7df50d4256c4cbde4ef4ae9931042b1e44ff13aeb5107a7e0e9ee07e0fbfc236
     SFP SRKHR0 = 7df50d42
     SFP SRKHR1 = 56c4cbde
     SFP SRKHR2 = 4ef4ae99
     SFP SRKHR3 = 31042b1e
     SFP SRKHR4 = 44ff13ae
     SFP SRKHR5 = b5107a7e
     SFP SRKHR6 = 0e9ee07e
     SFP SRKHR7 = 0fbfc236
```

The tools are provided to create the signature file and embed the signature at end of header file.

10.3.4.3.1 gen_sign

This tool is provided for the user to calculate signature for a given hash using CST tool. The tool requires only the hash file and private key file from the user as input. It would generate signature file as output.

It uses RSA_sign API of openssl to calculate signature over hash provided.

Usage

./gen_sign [option] <HASH_FILE> <PRIV_KEY_FILE>

--sign_file SIGN_FILE	Provide file name for signature to be generated as operand. SIGN_FILE is generated containing signature calculated over hash provided through HASH_FILE using private key provided through PRIV_KEY_FILE. With this option HASH_FILE and PRIV_KEY_FILE are compulsory while SIGN_FILE is optional. SIGN_FILE default value is signout.
HASH_FILE	Name of hash file containing hash over signature needs to be calculated.
PRIV_KEY_FILE	Name of key file containing private key

Usage Example

After the hash file has been created as described in Signature generation on page 2129, the tool can be used as described below:

```
$ ./uni_sign --img_hash input_files/uni_sign/<platform>/input_uboot_nor_secure
.
.
.

*********************************************
* Image Hash Stored in File: hash.out
* Header File is w/o Signature appended
*********************************************

Header File Created: hdr_uboot.out

$ ./gen_sign hash.out srk.pri

    #-----------------------------------------------------#
    #-------         --------     --------        -------#
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #-----------------------------------------------------#
Signature Length = 80
Hash in hash.out is signed with srk.pri
Signature is stored in file : sign.out
```

10.3.4.3.2 sign_embed

This tool embeds signature in the header file generated using img_hash option which generates header but doesn't embed signature in the header. This option opens header file and copies signature at the end of the file.

The header file generated with 'img_hash' option has padding added till signature offset, so that signature can be directly embedded to the end of the file.

Usage

./sign_embed <hdr_file> <sign_file>

hdr_file	Name of header file in which signature needs to be embedded
sign_file	Name of sign file containing signature which needs to be embedded

Usage Example

```
$ ./sign_embed hdr_uboot.out sign.out

    #-----------------------------------------------------#
    #-------         --------     --------        -------#
    #------- CST (Code Signing Tool) Version 2.0  -------#
    #-------         --------     --------        -------#
    #-----------------------------------------------------#

hdr_uboot.out is appended with file sign.out (0x80)
```

NOTE

User can generate the complete header along with signature in a single step using uni_sign/uni_pbi tool without any option.

./uni_sign <input_file>

OR

User may wish to do it in three seperate steps:

1. ./uni_sign **--img_hash** <input_file> (Create header file without signature and store the Hash in a separte File)
2. ./gen_sign[44] [option] <HASH_FILE> <PRIV_KEY_FILE> (Sign the Image Hash using Private Key)
3. ./sign_embed <hdr_file> <sign_file> (Embed the signature at the end of header file)

[44] This may be done by user's own tool in case he doesn't want to share the Private Key with the CST Tool.

Virtualization

11.1 Hypervisor

11.1.1 NXP Embedded Hypervisor Release Notes

NXP Embedded Hypervisor Release Notes

Software Version: 1.3

Date: 05/29/2014

Contents

1. Introduction
2. References
3. Changes
4. Limitations

---

1. Introduction

   This file documents the known limitations with the NXP Embedded Hypervisor version 1.3 release.

   Please refer to the Embedded Hypervisor Software User's Manual [2] and the Embedded Hypervisor Software Reference Manual [1] for complete details on the hypervisor software.

2. References

   a. NXP Embedded Hypervisor Software Reference Manual

   b. NXP Embedded Hypervisor Software User's Manual

3. Changes

   The following list summarizes changes in v1.3-009 of the NXP Embedded Hypervisor since release v1.3-008:

   - introducing "fast tlb1 feature" - the performance of TLB1 emulation is significantly improved by implementing a shorter code path for non-IPROT TLB1 entries. This is particularly useful for guests making heavy use of tlb1, for example when using indirect tlb1 entries. The feature is controlled by a Kconfig option and is enabled by default.
   - EPCR[DGTMI] (disable guest tlb management instructions) is now dynamically controlled
   - workaround A-006958 time-base erratum
   - workaround A-007907 l1 stash on e6500 erratum
   - workaround A-008007 t1040 pvr erratum
   - workaround A-00598 pamu erratum
   - workaround t1040 uart fifo erratum
   - other misc fixes

   The following list summarizes changes in v1.3-008 of the NXP Embedded Hypervisor since release v1.3-003:

- e6500 rev2 core support
- added emulation for PWRMGTCR0 introduced by e6500 rev2
- added Kconfig option for maximum number of supported partitions, defaulting to 24. Previous hard-coded limit was 8.
- fixed issue with guest tlb1 management structures state becoming out-of-sync. The issue triggered when a tlb1 entry was evicted.

The following list summarizes changes in v1.3-003 of the NXP Embedded Hypervisor since release v1.2-003:

- initial e6500 core support featuring MMUv2, LRAT, hardware page table walk
- initial multi-threading support on e6500 cores: each thread shows up in guest as a single threaded e6500 core
- added options in the HV config file to configure TLB behavior:
  - direct-guest-tlb-miss: tlb misses directed to the guest
  - direct-guest-tlb-mgt: tlb management instructions (tlbwe, tlbilx) are allowed in guest
- tlb0 caching is disabled on e6500 cores (support for this is not useful and would impact performance on other platforms)
- added support for the following T4xxx hw blocks: mpic, guts, ccf, cpc
- updated driver model to support multiple compatibles per driver
- added support for cache-able spin-table, epapr conformance
- added support to handle altivec exceptions
- reduced hypervisor's binary image footprint by ~400KB
- added shared l1 cache "shared resource synchronization" as defined and required in "e6500 Core RefMan, chapter 3.3.3.1"
- fixed a memory corruption happening on 64-bit targets
- fixed to work with newer gcc versions
  - r3 register was clobbered in bootstrap code thus the pointer to the device tree was lost
  - .notes section added in linker script
- fixed a long-standing l2 flush timeout issue on 64-bit targets
- many e6500 core related unit test updates
- libos: added a simple hardware threads api and example
- libos: introduced a cpu capability querying api

4. Limitations
   a. Boot Services
      - ELF file format-- the hypervisor image loader only supports ET_EXC as per the ePAPR. The ET_DYN flag is not supported.
   b. Configuration
      - The stashing may not be configured correctly if the hypervisor creates a binding between CPU and qman portal different than the one defined in the hardware device tree.
   c. Debug Services
      - Verbose log levels may not function correctly with all logging groups.
      - The GDB stub does not support using software breakpoints to debug multi-CPU partitions. 2 hardware breakpoints are supported.
      - The GDB stub does not support 'read' data breakpoints (rwatch command).

- In 'guest debug mode' debug stubs cannot share the debug resources (registers, interrupt) with the virtual CPU.
- The GDB stub does not support single stepping (stepi) over emulated instructions.

d. Tools

- the partman load command does not support compressed uImage files
- partman does not support loading images at guest physical addresses bigger than 4GB
- partman does not support loading images bigger than 3GB

11.1.2 NXP Embedded Hypervisor Software Reference Manual

11.1.2.1 Preface

About This Book

This document is a reference manual for the NXP Embedded Hypervisor software.

Audience

Developers or system architects that need to understand the interfaces and architecture of the NXP Embedded Hypervisor architecture.

Organization

A summary of the organization of this document is below:

- Introduction on page 2137 contains an introduction to the software architecture.
- The following sections describe the features and services of the hypervisor architecture available to a guest OS executing in a partition.
  - vcpu (Virtual CPU) on page 2139 describes the features of the vcpu relative to an physical CPU. The vcpu is the 'virtual' CPU in a partition upon which guest operating systems execute.
  - Partitions and partition management on page 2147 describes aspects of partitioning, including—the lifecycle of a partition, the initial state of a partition, how hardware resources are partitioned, guest device trees, and partition management.
  - ePAPR virtualization on page 2158 describes the hypervisor services compatible with the ePAPR virtualization standard. These services include—PIC, byte channels, and interpartition doorbells.
  - NXP hypervisor services on page 2171 describes NXP-specific hypervisor services available to guest operating systems. These services include—partition management, power management, and high availability services.
- The following sections describe additional features of the architecture
  - Configuration on page 2209 describes how the hypervisor is configured including the definition of partitions.
  - Debugging on page 2234 describes the debug interfaces to the hypervisor—the console and GDB stub interface.
  - Byte-Channel Serial Multiplexer Protocol on page 2237 describes the serial multiplexer protocol used by the byte-channel multiplexer.
  - Linux hypervisor management driver on page 2238 describes the hypervisor management driver API available for the Linux kernel.
  - Hypervisor Debug Stubs on page 2243 describes the programming interface available to create debug stubs that can be used to debug guest operating systems.
  - Hypervisor APIs on page 2245 describes hypervisor APIs available to debug stubs and other custom code added to the hypervisor
  - Hypervisor customization on page 2260 describes some hypervisor customization options for custom reset and system health monitoring

Conventions

This document uses the following conventions:

`Courier` is used to identify commands, explicit command parameters, code examples, expressions, data types, and directives.

Italic is used to identify key words in device trees.

All source code examples are in Device Tree Syntax (DTS) form.

11.1.2.2 Introduction

11.1.2.2.1 Overview

The NXP embedded hypervisor is a layer of software that enables the efficient and secure partitioning of a multicore system. A system's CPUs, memory, and I/O devices can be divided into groupings or *partitions*, as shown in the figure below. Each partition is capable of executing a guest operating system.

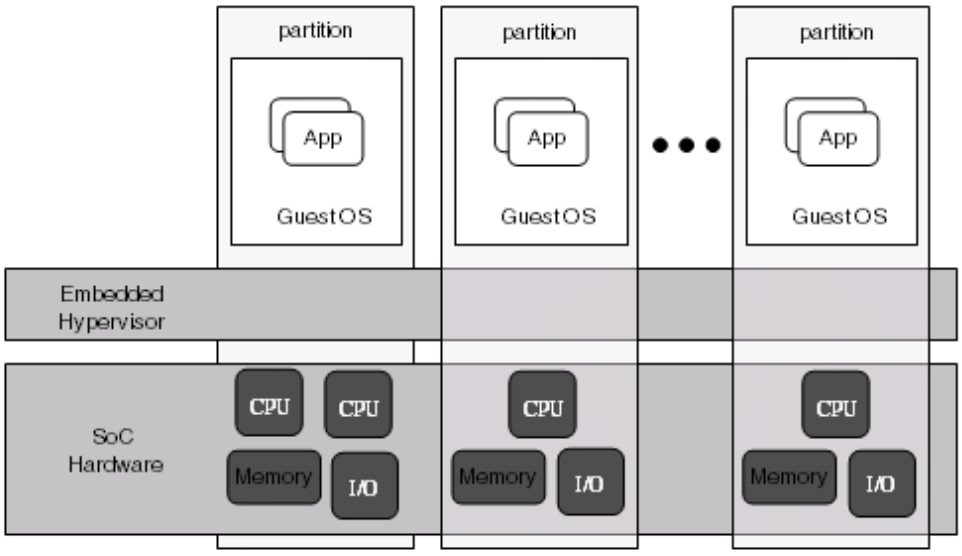

Figure 343. Partitioning with the Hypervisor in a Multicore Environment

Key features of the hypervisor architecture are summarized as follows:

- Partitioning. Support for partitioning of CPUs, memory, and I/O devices:
  - CPUs. Each partition is assigned one or more CPU cores in the system.
  - Memory. Each partition has a private memory region that is only accessible to the partition that is assigned the memory. In addition, shared memory regions can be created and shared among multiple partitions.
  - I/O devices. I/O devices may be assigned directly to a partition (Direct I/O), making the device a private resource of the partition, and providing optimal performance.
- Protection and isolation. The hypervisor provides complete isolation of partitions, so that one partition cannot access the private resources of another. The PAMU (an IOMMU) is owned and managed by the hypervisor to ensure device-to-memory accesses are constrained to allowed memory regions only.
- Sharing. Mechanisms are provided to selectively enable partitions to share certain hardware resources (such as memory).
- Virtualization. Support for mechanisms that enable the sharing of certain devices among partitions such as the system interrupt controller.
- Performance. The hypervisor uses the features of category Embedded.Hypervisor as defined by the Power ISA to provide security and isolation with very low overhead. Guest OSes take external interrupts directly without hypervisor involvement providing very low interrupt latency.
- Ease of migration. The hypervisor architecture uses a combination full emulation and para-virtualization to maintain high performance while requiring minimal guest OS changes when migrating code from an phyisical CPU to running as a guest under the hypervisor on the vcpu.

11.1.2.2.2 Software Architecture Overview

The hypervisor provides the capability to create partitions in which guest software can execute in isolation without the possibility of interference from other partitions in the system.

The hypervisor architecture consists of the following key components:

- Virtual CPU (vcpu)—Software executing in a partition under the hypervisor sees a CPU that is nearly identical to the physical CPU, except for some CPU state and features which are hypervisor privileged and not accessible.
- Hypercall services—Some services are provided via hypercalls, including: the interrupt controller, byte-channels, interpartition doorbells, IOMMUs, and partition management.
- Boot services—The hypervisor adopts the device tree and multicore boot architecture of the power.org ePAPR specification. This defines mechanisms for resource discovery within a partition and for starting multiple CPUs in a single partition.
- Debug services—Guest software that has its own debug stub can use the stub without change through the capabilities of the vcpu. In addition, the hypervisor provides a gdb stub in the hypervisor that provides an interface for a host debugger to use to debug guest operating systems.
- Direct I/O—High-speed peripherals are not virtualized and are assigned and managed directly by partitions. External interrupts are taken by partitions directly with no hypervisor involvement.

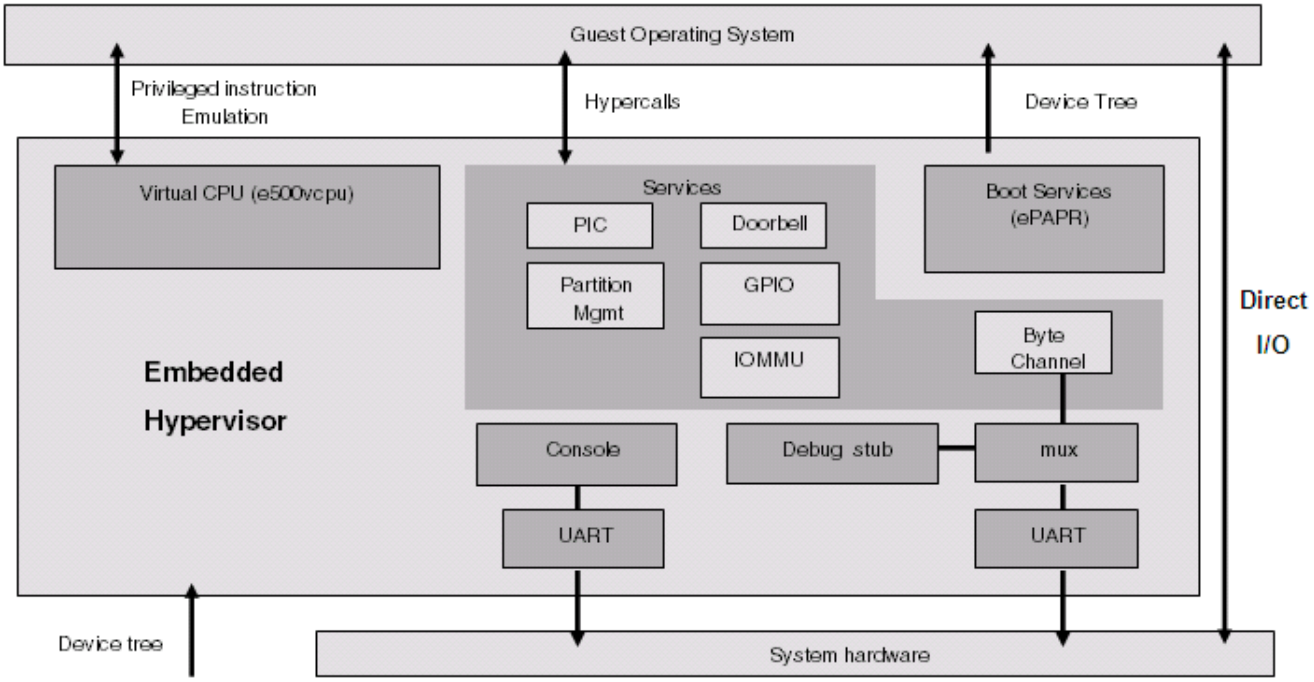

Figure 344. Hypervisor Block Diagram

11.1.2.3 vcpu (Virtual CPU)

11.1.2.3.1 vcpu Overview

Virtualization enables multiple operating systems to run on a system, each in their own isolated virtual machine. The Hypervisor creates and manages the virtual machines, one part of which is a virtual CPU (or vcpu). The vcpu emulates a physical CPU and the behavior of instructions, registers, and exceptions on the vcpu is nearly identical to the physical CPU being emulated.

There are a few minor architectural and programming model differences between the vcpu and the following physical CPUs:

- e500mc
- e5500
- e6500

For a description of the differences between vcpu and emulated CPU please review the *[6] NXP Power Architecture Book E Virtual CPU Specification*

This chapter describes the NXP Embedded Hypervisor specific considerations.

11.1.2.3.2 NXP Embedded Hypervisor Specific Considerations

11.1.2.3.2.1 vcpu configuration modes

A partition's configuration (see Partition Node Properties on page 2215) may specify configurable options for vcpus. This section describes several configurable modes available.

11.1.2.3.2.1.1 Guest Cache Lock Mode

The behavior of cache locking instructions (dcbtls, dcbtstls, dcblc, icbtls, icblc) is dependent on the setting of guest cache lock mode. When guest cache lock mode is enabled (the default), cache locking instructions are permitted to execute normally. If guest cache lock mode is disabled, executing cache-locking instructions is effectively a nop; the operation is ignored.

Guest cache lock mode is configured in the definition of a partition (see Partition Node Properties on page 2215) and guest software can determine the configuration of this mode from the guest device tree (see Hypervisor Node Properties on page 2153).

11.1.2.3.2.1.2 Guest Debug Mode

The availability of the debug resources (debug interrupt, IACx, DACx, DBCRx) of the vcpu is determined by the setting of guest debug mode. By default, guest debug mode is enabled.

When using a hypervisor-resident debug stub, guest debug mode can be disabled in a partition's configuration (see Partition Node Properties). Guest software can determine the configuration of this mode from the guest device tree (see Hypervisor Node Properties on page 2153) or by examining the DBCR0[EDM].

11.1.2.3.2.2 Registers

This section describes differences between the register model of the physical CPU and that of the vcpu.

11.1.2.3.2.2.1 Debug Registers

By default guest debug mode is enabled (see Guest Debug Mode on page 2140). When guest debug mode is disabled accesses to CPU debug registers are boundedly undefined.

In guest debug mode reads from all debug registers are supported.

11.1.2.3.2.2.2 Removed Registers

The registers listed in the table below are removed from the vcpu. Attempting accesses to one of these registers yields boundedly undefined results.

Table 392. Removed Registers

SPR Number	Name	Description
311	MSRP	MSR protect register
339	MAS5	MMU assist register 5
341	MAS8	MMU assist register 8
306	DBSRWR	Debug status register write register
307	EPCR	Embedded hypervisor control and status Only if 64-bit category is not supported.
338	LPIDR	logical partition id Register
432	IVOR38	Interrupt vector offset register 38. Guest processor doorbell
433	IVOR39	Interrupt vector offset register 39. Guest processor doorbell critical
434	IVOR40	Interrupt vector offset register 40. Embedded Hypervisor system call
435	IVOR41	Interrupt vector offset register 41. Embedded Hypervisor privilege
436	IVOR42	Interrupt vector offset register 42. LRAT error interrupt

Table continues on the next page...

Table 392. Removed Registers (continued)

SPR Number	Name	Description
447	GIVPR	Guest interrupt vector prefix register
382	GPIR	Guest processor identification register
440	GIVOR2	Guest interrupt vector offset register 2. Guest data storage interrupt.
441	GIVOR3	Guest interrupt vector offset register 3. Guest instruction storage interrupt.
442	GIVOR4	Guest interrupt vector offset register 4. Guest external input.
443	GIVOR8	Guest interrupt vector offset register 8. Guest system call interrupt.
444	GIVOR13	Guest interrupt vector offset register 13. Guest data TLB error.
445	GIVOR14	Guest interrupt vector offset register 14. Guest instruction TLB error.
383	GESR	Guest exception syndrome register
378	GSRR0	Guest save/restore register 0
379	GSRR1	Guest save/restore register 1
381	GDEAR	Guest DEAR
380	GEPR	Guest EPR
368-371	GSPRG0-3	Guest SPR general 0-3

If guest debug mode is disabled, the register below does not exist and attempted accesses yield boundedly undefined results.

Table 393. Registers Absent when Guest Debug Mode is Disabled

SPR Number	Name	Description
415	IVOR15	Interrupt vector offset register 15. Debug

11.1.2.3.2.3 Instruction model differences

The set of instructions and their behavior on the vcpu is identical to the physical CPU except as described in this section.

11.1.2.3.2.3.1 Instruction Model Overview

The vcpu supports four interrupt levels like the physical CPU.

- Noncritical
  - System call
  - Program
  - Alignment
  - External input
  - ISI

  - DSI
  - Decrementer
  - Fixed interval timer
  - Data TLB error
  - Instruction TLB error
  - Doorbell
  - Floating point unavailable
  - Performance monitor
- Critical
  - Watchdog
- Machine check
  - Machine check
- Debug
  - Debug

All interrupt definition and exception behavior in the vcpu is identical to the physical CPU except as described below:

- The following interrupts are hypervisor-only resources and do not exist in the vcpu:
  - Guest processor doorbell
    - Result of access to IVOR38 is boundedly undefined
  - Guest processor doorbell critical
    - Result of access to IVOR39 is boundedly undefined
  - Embedded Hypervisor system call
    - Result of access to IVOR40 is boundedly undefined
  - Embedded Hypervisor privilege
    - Result of access to IVOR41 is boundedly undefined
  - LRAT error
    - Result of access to IVOR42 is boundly undefined
- The existence of the debug interrupt depends on a configurable mode of the vcpu:
  - The vcpu's guest debug mode (see Guest Debug Mode on page 2140) enables and disables debug interrupts
  - MSR[DE] is read-only if guest debug mode (see Guest Debug Mode on page 2140) is disabled.
- A memory access to physical address location that is invalid or does not exist results in a machine check interrupt at the vcpu.

11.1.2.3.2.4 Memory management

11.1.2.3.2.4.1 Memory Management Overview

All memory management in the vcpu is identical to the physical CPU except for the following:

- Unlike the physical CPU, which uses a 48-bit virtual address (e500mc), 80-bit virtual address (e5500) or 86-bit virtual address(e6500) the vcpu address translation uses a 41-bit virtual address on e500mc, 73-bit virtual address on e5500 and 79-bit virtual address on e6500. The TLPID and TGS fields in the physical CPU virtual address do not exist in the vcpu.

- The MAS5 (MMU Assist 5) register defines TLB search values and is accessible only by the hypervisor. Attempted access by guest software are boundedly undefined.
- The MAS8 (MMU Assist 8) register defines state for TLB accesses and is accessible only by the hypervisor. Attempted access by guest software are boundedly undefined.
- The EGS and ELPID fields in EPLC and EPSC are not writeable.
- The NENTRY field in TLB1CFG may report a smaller number of TLB entries compared to the hardware
- The NENTRY field in TLB0CFG is zero—indicating that number of entries in TLB0 is implementation defined and not visibible to software.
- The width of the LPID as reported by MMUCFG is zero.
- Using the **tlbre** instruction to read TLB entries from TLB0 is boundedly undefined.
- Execute-only TLB mappings (not readable, not writeable) as not supported

Programming Notes

- The use of the **tlbivax** instruction is deprecated—it is recommended that **tlbilx** be used instead. This requires guest OSes to use intercore signaling to synchronize TLB invalidates, but avoid the need for using **tlbsync**.
- It is recommended that tlbilx be used for all invalidations of TLB0. Using **tlbwe** to clear a TLB entry's valid bit may have additional performance costs depending on the hypervisor software implementation.
- **tlbsync**—guest OS software is not required to take steps to synchronize **tlbsync** instructions across cores or partitions. The vcpu handles synchronization to ensure that only one **tlbsync** is in flight in the platform.
- The timing of the TLB management instructions may be different compared to the physical CPU.
- Note: the vcpu may internally cache more virtual-to-physical mappings than exist in the hardware TLB. Software should not make any assumptions about the number TLB mappings present in the vcpu. Invalidation of a TLB entry should be explicit.
- Note: If guest tlb management instructions are allowed tlbilx cannot be used to invalidate TLB1 entries. In this case tlbilx is executed in guest state, but all the TLB1 entries are invalidation protected (configured as such by the Hypervisor).

11.1.2.3.2.4.2 Guest TLB management

e6500 core allows guest TLB management instructions. In this case tlbwe and tlbilx are executed directly by the guest. Two partition configuration options allow for different configuration options:

- direct-guest-tlb-management - if present indicates that tlbwe and tlbilx can be executed in guest state
- direct-guest-tlb-miss - if present indicates that the TLB miss interrupts are taken directly by the guest

These two options can be enabled in various combinations:

Table 394. Guest TLB management options

direct-guest-tlb-management	direct-guest-tlb-miss	Comments
0	0	• provides the highest level of architectural correctenss • LRAT will still be used in this mode if the guest is using hardware page table walk • tlbilx can be used to invalidate TLB1 • no restriction on physical contiguity of guest memory

Table continues on the next page...

Table 394. Guest TLB management options (continued)

1	0	• tlbilx cannot be used to invalidate TLB1 • no restriction on physical contiguity of guest memory (e.g. TLB1 entries could be backed by smaller pages) • no HV mediation for TLB write unless an LRAT miss occur
1	1	• tlbilx cannot be used to invalidate TLB1 • restrictions on physical contiguity of guest memory • no HV mediation for TLB write unless an LRAT miss occur
0	1	• tlbilx can be used to invalidate TLB1 • restrictions on physical contiguity of guest memory • LRAT will still be used in this mode if the guest is using hardware page table walk

11.1.2.3.2.4.3 Invalid MMU Mappings

The hypervisor validates all physical address mapped by guest software. If guest software maps a physical address that does not belong to its partition the behavior is as follows:

- The **tlbwe** instruction completes normally and writes the mapping into the TLB
- The entry can be read with a **tlbre** instruction
- When guest software accesses the invalid mapping a machine check occurs

For page table walk originated bad mappings a machine check is reflected to the guest when the attempt to add in TLB a bad mapping is made by the hardware. In this case the entry is not added in the TLB.

11.1.2.3.2.4.4 Memory Management Address Translation

The vcpu MMU translates effective addresses generated by loads, stores, and instruction fetches into real addresses (used for memory bus accesses) using an interim virtual address as indicated by the following table.

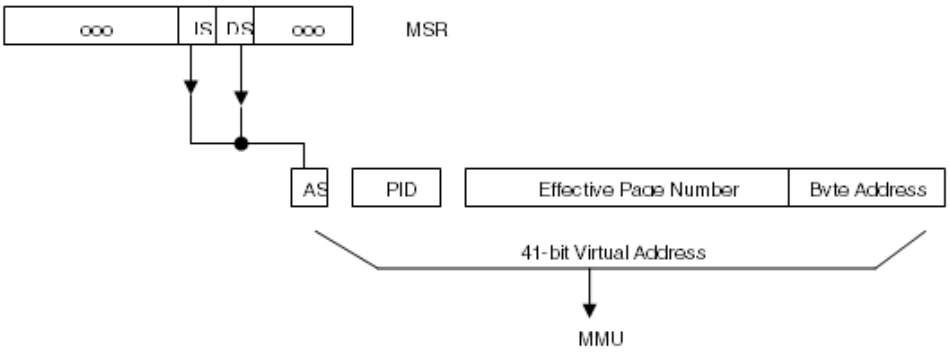
Table 395. Address Translation

	Effective address	Real address	Virtual address
e500mc	32	36	41
e5500	64	36	73
e6500	64	40	79

Address translation in the vcpu architecture starts with an effective address that is prepended with an address space (AS) value and a process ID (PID) to construct a virtual address (VA). The virtual address is then translated into a real address based on the translation information found in the on-chip TLB. As shown in the figure below, the AS bit for the access is selected from the value of MSR[IS] or MSR[DS], for instruction or data accesses, respectively.

The GS (guest state) and LPID (logical partition id) components of an physical CPU virtual address are not supported.

Figure 345. Address Translation



11.1.2.3.2.5 Timers

11.1.2.3.2.5.1 Timebase

The processor timebase (TBU/TBL) is automatically synchronized by the hypervisor across all physical CPUs managed by the hypervisor.

Unlike the physical CPU, in the vcpu TBU/TBL are not writeable. An attempt to write TBU/TBL is boundedly undefined.

11.1.2.3.2.5.2 Decrementer

The decrementer register and exception are identical to the physical CPU —a decrementer interrupt will occur when a decrementer exception exists and MSR[EE] = 1.

11.1.2.3.2.5.3 Fixed Interval Timer

The fixed interval timer configuration and behavior is identical to the physical CPU —a fixed interval timer interrupt will occur when a fixed interval timer exception exists and MSR[EE] = 1.

11.1.2.3.2.5.4 Performance Monitor

The performance monitor registers (PMRs) and performance monitor interrupt are identical to the physical CPU with the following caveat:

It is boundedly undefined if the guest alters MSR[PMM] when a perf interrupt is pending, including while the interrupt is being serviced, before the condition has been cleared.

11.1.2.3.2.5.5 Watchdog Timer

The vcpu provides a standard e500 watchdog timer:

- TCR[WPEXT] is concatenated with TCR[WP] to select a bit that triggers the watchdog timer
- TCR[WIE] enables watchdog timer interrupts
- The TSR[ENW] and TSR[WIS] bits behave normally—on first watchdog expiration a watchdog interrupt is generated (gated by MSR[CE] and TCR[WIE]). On the second time out TCR[WRC] governs the behavior.
- TSR[WRS] reflects TCR[WRC] on a watchdog generated reset.

The behavior of TCR[WRC] is different on the virtual CPU than on the physical CPU .

vcpu WRC definition:

- 00 No watchdog reset will occur
- 01 Partition reset (may be overridden by *watchdog-timeout*)
- 10 Partition reset (may be overridden by *watchdog-timeout*)

- 11 Partition reset (may be overridden by *watchdog-timeout*)

NOTE

one virtual CPU's watchdog expiration results in the entire partition being reset, not just the vcpu that timed out.

When a partition reset occurs, the virtual CPU that caused the watchdog reset will have its TSR[WRS] set to reflect TCR[WRC].

The action taken on the second watchdog timeout is governed by the value of WRC and the property *watchdog-timeout* on the partition node defining a partition (see Partition Node Properties on page 2215). A WRC nonzero value causes the current partition to reset unless the *watchdog-timeout* property is specified. See Partition Node Properties on page 2215 for allowable policies for *watchdog-timeout*.

11.1.2.3.2.6 Debug

All processor core debug features, including debug exception and interrupts are available unless guest debug mode is disabled (see Guest Debug Mode on page 2140).

MSR[DE] is read-only if guest debug mode is disabled, otherwise MSR[DE] is writeable and enables debug interrupts.

The vcpu supports a subset of the Power ISA embedded debug exceptions:

- Trap
- Instruction address compare
- Data address compare
- Instruction complete
- Branch taken

The following e500mc debug events are not supported:

- Return from interrupt
- Interrupt taken
- Unconditional debug event

The debug interrupt and supported debug function in a manner identical to the physical CPU.

11.1.2.3.2.7 Hardware Threads

On multi-threaded cores, the Hypervisor exposes the vcpu to guests as a single-threaded core. The thread management instructions (mftmr, mttmr), SPRs and TMRs are emulated by the Hypervisor: reads behave as if the core is single-threaded while writes are unsupported and trigger a warning in the Hypervisor console. Tables below list the supported SPRs and TMRs and the results of reads and writes.

Table 396. Supported SPRs

SPR Number	SPR	Read	Write
437	TENSR	1	Warning
438	TENS	1	Warning
439	TENC	1	Warning
446	TIR	0	Warning

Table 397. Supported TMRs

TMR Number	TMR	Read	Write
16	TMCFG0	0101h	Warning
288	IMSR0	Warning	Warning
289	IMSR1	Warning	Warning
320	INIA0	Warning	Warning
321	INIA1	Warning	Warning

11.1.2.4 Partitions and partition management

11.1.2.4.1 Partitions and Partition Management Introduction

A partition is a logical grouping of physical and virtual resources in which an operating system can securely run.

- Physical resources in a partition include CPUs, memory, and I/O devices.
- Virtual resources include hypervisor provided services such as byte-channels, interpartition doorbells, and interrupt controller services.

A partition generally is in one of two primary states:

- Stopped—the state of a partition after it has been created, exited, or stopped. A *stopped* partition is initialized and resources allocated to it, but is not running. A *stopped* partition can be started.
- Running—the state after control has been transferred to the partition on the partition's boot CPU. A running partition can be stopped or restarted.

In addition, two transitory states (starting, stopping) exist when a partition is being created or transitioning between the two primary states. In the *starting* and *stopping* states, no partition management actions are permitted.

The figure below shows the valid states of a partition and the actions that result in a state transition.

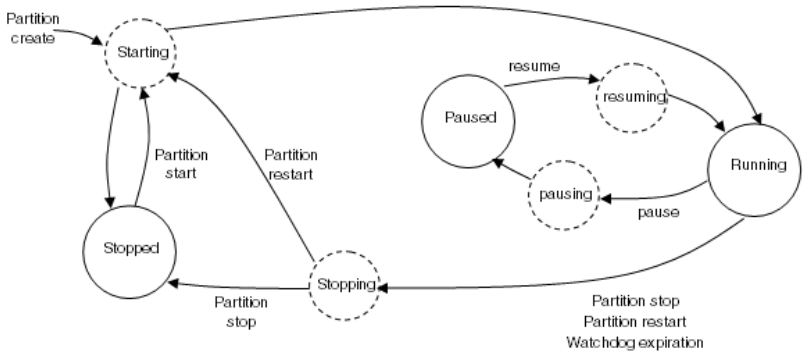


Figure 346. Partition State Diagram

A *paused* state also exists for debugging purposes. A paused partition executes no instructions and can take no interrupts. Pause and resume of partitions can be done by using the hypervisor's command shell.

11.1.2.4.2 Hardware and Guest Device Trees

The hypervisor is passed an ePAPR-compliant hardware device tree (from boot firmware, such as u-boot) when it is booted that describes all the hardware in the system.

A separate binary blob of configuration information is passed by address to the hypervisor which contains all hypervisor configuration parameters and partition definition information. This information is referred to as the "hypervisor configuration tree". Based on the hypervisor configuration tree the hypervisor will create partitions. The hypervisor will dynamically create guest device trees for each partition.Guest device trees describe the CPUs, memory, I/O devices, and other virtual resources that below to the partition.

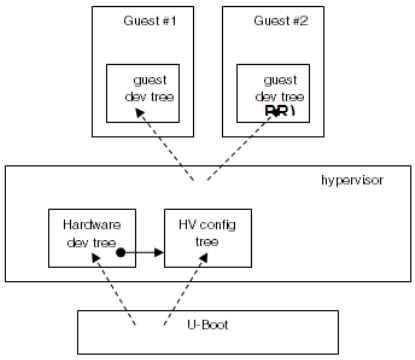

Figure 347. Device Tree Overview

Hypervisor configuration and the definition of the hypervisor configuration tree is described in Configuration on page 2209.

Guest device trees are described in detail in Partitions and partition management on page 2147 and in ePAPR virtualization on page 2158

11.1.2.4.3 Partition Physical Addresses (Guest Physical)

Guest software executing in a partition sees a physical address space created by the hypervisor that may not correspond directly to true physical addresses (real addresses in the Power Architecture) in the system hardware. These addresses are referred to as guest physical addresses (logical addresses in the Power Architecture). For example, each partition may have memory at guest physical address 0x0—where in each partition address 0x0 that corresponds to a unique true physical address.

This mapping of guest physical to true physical is specified in the definition of a partition and is maintained by the hypervisor and is completely transparent to guest software. Guest software becomes aware of the guest physical address ranges available to it via the guest device tree passed to the partition at initialization.

11.1.2.4.4 Hardware Resource Partitioning

Each hardware resource or I/O device is allocated in one of several ways:

- Direct access—The resource is directly accessible by guest software without hypervisor intervention. In the case of I/O devices, this means the device is assigned to a partition and becomes a private resource of the partition.
- Hypervisor-managed access—The hypervisor provides a service (via hcall or emulation) that enables partitions to access the resource

The table below identifies both CPU and I/O device resources on the SoC and the type of allocation.

Table 398. CPU and I/O Partitioning

Hardware Feature	Direct Access	Provided by hcall	Provided by Emulation	Hypervisor Only
CPU Resource

Global Utilities				X4
DDR SDRAM Controllers				X4

NOTE

1. In guest debug mode, guest software manages the CPU debug resources with the hypervisor providing the resources via emulation.
2. When guest debug mode is disabled, the hypervisor owns the CPU debug resources and they are not accessible by guest software
3. The I2C controllers can be configured to be owned by a single partition for direct access. Each controller can be assigned to a different partition with an emulated service provided by the hypervisor.
4. A recommended configuration. The system architect is free to assign any region of CCSR space to a partition through the partition's device tree.
5. In a typical configuration one DUART is allocated to the hypervisor for console and byte-channel services. Any remaining DUARTs are available for direct assignment to a partition.
6. Byte-channel services provide virtualized character I/O capabilities.
7. Some L1 and L2 cache control features are hypervisor only, others are provided by emulation.
8. The ability for guests to perform cache-locking operations is dependent on whether guest cache lock mode is enabled.
9. Guest software gets direct access to the performance monitor resources. However, due to some hardware quirks the hypervisor does trap/emulate accesses to the performance monitor registers while a perfmon interrupt is pending.
10. Certain HID0 bits are accessible to guests, and others are hypervisor only.
11. e6500 allows direct tlb management instructions. In this case tlbwe and tlbilx will be directly executed by the guest.

11.1.2.4.5 Guest device trees

11.1.2.4.5.1 Guest Device Trees Overview

Partitions discover the hardware and virtual resources available to them through a guest device tree loaded into their memory at partition initialization. The physical and logical structure of the device tree complies with the ePAPR specification (power.org's standard for *Embedded Power Architecture Platform Requirements, 1.0*).

All guest device trees will have the following nodes:

- A root node
- A cpus node with one or more child CPU nodes as defined in the ePAPR. The CPU nodes are standard for the underlying hardware and are described in the binding documentation for the physical CPU.
- A interrupt controller node if the partition has interrupt generating I/O devices.
- A memory node as defined in the ePAPR. Specifies the physical address and size of memory belonging to the partition.
- A hypervisor node

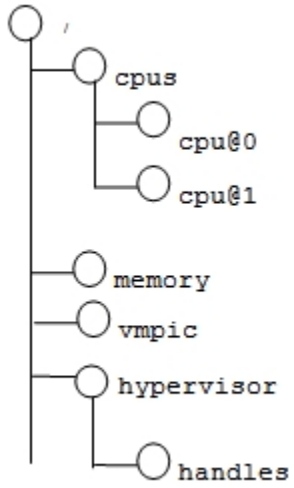

Figure 348. Figure 3-4. CPU, Memory, and Hypervisor Nodes Example

The guest device tree may have other nodes representing physical or virtual resources.

All physical addresses in the guest device tree are guest physical addresses (see Guest device trees on page 2151)

11.1.2.4.5.2 Root Node

The root node of a guest device tree has the properties listed in the table below.

Table 399. Root Node Properties

Property Name	Usage	Value Type	Definition
#address-cells	R	<u32>	Must be 2. Specifies the number of <u32> cells to represent the address in the *reg* property in *children* of root.
#size-cells	R	<u32>	Must be 2. Specifies the number of <u32> cells to represent the size in the *reg* property in *children* of root.
compatible	R	<stringlist>	Value consists of the compatible string list from the hardware device tree with the string "-hv" appended.
epapr-version	R	<string>	Must be epapr-version = "ePAPR-1.0"
label	R	<string>	Text label describing the partition. This value is propagated from the *label* property on the partition node that defines the partition.
Usage legend: R = Required, O = Optional, OR = Optional but recommended, SD = See definition			

11.1.2.4.5.3 CPU node

CPU nodes are as defined by the ePAPR.

11.1.2.4.5.4 Memory node

Memory nodes are as defined by the ePAPR.

11.1.2.4.5.5 Interrupts and the VMPIC Node

If a partition has interrupt generating I/O devices it will have an ePAPR virtual interrupt controller node.

11.1.2.4.5.6 Guest Device Trees Hypervisor Node

11.1.2.4.5.6.1 Hypervisor Node Properties

Each guest device tree has a hypervisor node located at the root of the tree. The following table defines properties that may be present on the hypervisor node.

Table 400. Hypervisor Node Properties

Property Name	Usage	Value Type	Definition
fsl,hv-version	R	<prop-encoded-array>	Specifies the version of the hypervisor. The value is a prop-encoded-array consisting of 4 cells defined as follows: <*major-version, minor-version, hcall-version, hcall-last-comp-version*> Where: • *major-version* is a <u32> value specifying the major version number of the hypervisor software (e.g. for version 1.02 major version is 1) • *minor-version* is a <u32> value specifying the minor version number of the hypervisor software • *hcall-version* is a <u32> identifying the version of the hcall interface. • *hcall-last-comp-version* is a <u32> identifying the lowest version number of the hcall interface which the hypervisor is backwards compatible with
fsl,hv-guest-cache-lock-disable	O	<none>	If present defines that guest cache lock mode is disabled.
fsl,hv-guest-debug-disable	O	<none>	If present defines that guest debug mode is disabled.
fsl,hv-pic-legacy	O	<none>	If present specifies that the partition uses the legacy interface between the CPU and interrupt controller (i.e., does **not** use the interrupt proxy functionality and Coreint interface).
fsl,hv-sys-reset-status	R	<string>	The *fsl,hv-sys-reset-status* property is set on the /hypervisor node of the guest device to convey to a partition the most recent reason the system hardware was reset. The values below define the hardware reset status—i.e. why the system hardware was reset. One of the hardware reset value will always be set. "**power-on-reset**"—The partition was reset due to a power on reset of the system hardware "**hard-reset**"—The partition was reset due to a hard reset of the system hardware

Table continues on the next page...

Table 400. Hypervisor Node Properties (continued)

Property Name	Usage	Value Type	Definition
fsl,hv-reason-stopped	R	<string>	The *fsl,hv-reason-stopped* property is set on the /hypervisor node of the guest device to convey to a partition the most recent reason the partition was stopped. Valid values are described below: **"stop"**—The partition was stopped due to a stop request (via hcall or shell). **"restart"**—The partition was stopped and restarted due to a restart request. **"watchdog"**—The partition was stopped and restarted due to a watchdog expiration. This property will not be present until a partition has been stopped/restarted for the first time.
fsl,hv-stopped-by	R	<string>	The value defines one string which identifies what component was responsible for the reason stopped set in the fsl,hv-reason-stopped property. Valid values are described below: **"self"**—The partition was stopped/restarted by the partition itself. **"manager"**—The partition was stopped/restarted by a partition manager. **"shell"**—The partition was stopped/restarted by the hypervisor command shell. This property will not be present until a partition has been stopped/restarted for the first time.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.4.5.6.2 Handles

A handles node exists under the /hypervisor node to represent virtual resources made available to the guest via a handle. For example:

- Byte-channels. See Byte-channel Services on page 2167 for a description of how byte-channels are represented in guest device trees.
- Interpartition doorbells. See Inter-partition doorbells on page 2169 for a description of how interpartition doorbells are represented in guest device trees.
- Partition nodes. Partition can be configured to perform partition management tasks on other partitions. A partition node provides a handle to managed partitions. See Partition Management Guest Device Tree Representation on page 2176 for a description of how managed partitions are represented in guest device trees.

11.1.2.4.6 Partition Creation

Partitions are defined using the hypervisor configuration tree—this is a tree data structure that describes the CPUs, memory, hardware I/O devices, and virtual resources that define the partition. See Partition definition on page 2215 for details on how partitions are defined.

Partitions are created during hypervisor initialization.

11.1.2.4.7 Partition Start

Partition **start** moves a created partition from the stopped state into the running state, which is the normal execution state of a partition.

This occurs in one of two ways:

- Auto-started. Partition start can occur automatically at hypervisor initialization for partitions defined in the hypervisor configuration tree. When the hypervisor starts the partition it automatically loads all OS images and supplementary images specified in the partition definition in the hypervisor configuration tree (see the guest-image, linux-rootfs, and load-image-table property in the partition definition in the hypervisor configuration tree. If the guest-image property is defined the partition is auto-started unless the no-auto-start property is used.
- Manager partition. A manager partition using the FH_PARTITION_START hcall. It is assumed that prior to starting the partition that all OS and supplementary images are loaded by the partition manager unless the load parameter is specified.

The hypervisor shell can also be used to start partitions, which may be useful during development and debugging.

11.1.2.4.8 Partition Restart

A partition in the running state can be restarted. A restart operation involves stopping the partition, reloading OS images, and starting (partition moves into the running state).

A restart action can come from several sources:

- A partition can ask for an explicit restart of itself via the FH_PARTITION_RESTART hcall
- Watchdog expiration can be configured to cause a partition restart
- A manager partition can restart a partition via the FH_PARTITION_RESTART hcall
- A debug stub may restart a partition.

This occurs in one of two ways:

- For auto-started partitions (see Partition Start on page 2155) the hypervisor performs the full restart sequence—stopping the partition, reloading all OS images and supplementary images, and starting the partition. In this case the partition never moves into the stopped state, but transitions directly from the stopping state to the starting state.
- For partitions that do not have a guest-image property and are managed, a restart causes the partition to be moved into the stopped state and an interrupt is sent to the manager indicating that a restart is requested.

Note: The no-auto-start property affects the initial boot only and not partition restarts.

The hypervisor shell can also be used to restart partitions, which may be useful during development and debugging.

11.1.2.4.9 Partition Stop

Partition stop moves a created partition from the running state into the stopped state.

This occurs in one of two ways:

- A partition may stop itself by using the FH_PARTITION_STOP hcall.
- A manager partition can stop a managed partition using the FH_PARTITION_STOP hcall. Note: this does not cause a clean shutdown of the target partition, but immediately halts the partition.
- A watchdog expiration with a policy configured to stop the partition

A stopped partition will have all interrupts source disabled at the interrupt controller and DMA will be disabled for all devices at the IOMMU unless the no-dma-disable or defer-dma-disable properties are set (see Partition Node Properties on page 2215 and Device Configuration Nodes on page 2222 for additional details).

The hypervisor shell can also be used to stop partitions, which may be useful during development and debugging.

11.1.2.4.10 Partition state at initialization

This section summarizes the initial state of a partition.

11.1.2.4.10.1 Image loading

For auto-started partitions, the hypervisor provides flexible mechanisms for loading images from a memory-mapped location (e.g. flash or a dedicated region of RAM) into a partition prior to partition start.

The guest-image property on a partition node specifies the source and destination addresses of the image that contains the entry point to which control is transferred to when the partition is started. See Partition Node Properties on page 2215, for details on supported image formats and how the entry point is calculated.

The linux-rootfs property on a partition node and can be used to specify the location of a Linux root filesystem to be loaded. The hypervisor will set the appropriate Linux boot arguments on the /chosen bootargs property. See Partition Node Properties on page 2215, for additional details and supported image formats.

A load-image-table property is also supported that allows additional supplementary images to be loaded. See Partition Node Properties on page 2215, for additional details and supported image formats.

11.1.2.4.10.2 Initial Mapped Areas

The ePAPR defines a concept of an *initial mapped area* or IMA. A partition's IMA is the region of memory that contains the entry point for the guest. Both boot CPUs and secondary CPUs begin client program execution in an IMA. The terms Boot IMA and Secondary IMA (SIMA) are used to distinguish the IMAs for boot CPUs and secondary CPUs where necessary.

11.1.2.4.10.2.1 Boot IMA

By default the hypervisor will configure a boot IMA at guest physical address 0x0. As per the ePAPR, the MMU will be configured with the effective address of the boot IMA to be 0x0. This configuration requires that at least one guest physical memory area (GPMA) be defined at guest physical address 0x0 (see Guest Physical Memory Areas on page 2221).

The DTB window (see *dtb-window* property, in Partition Node Properties on page 2215) must be located in the boot IMA.

The size of the boot IMA is passed to the client in r7 as per the ePAPR.

The hypervisor provides additional flexible mechanisms for defining boot IMAs that are not ePAPR complaint. The *init-map-paddr, init-map-size*, and *init-map-vaddr* properties allow customization of the guest physical address, effective address, and size of the boot IMA.

11.1.2.4.10.2.2 Secondary IMA

The guest physical address of secondary IMAs is determined by the entry_address field specified in the spin table used to release secondary vcpus. The effective address will be 0x0. The secondary IMA will always be 4KiB in size.

11.1.2.4.10.3 Initial State of Virtual CPUs

In a partition with multiple vcpus, vcpu #0 is the boot CPU and all other vcpus in the partition are considered secondary. See the ePAPR for additional details on boot and secondary CPUs.

11.1.2.4.10.3.1 CPU Initial State

Within a partition, the initial state of the boot and secondary vcpus complies with the entry conditions specified in the ePAPR. The vcpu state is summarized below:

Table 401. vcpu Initial State

Register	Value
MSR	PR=0, supervisor state EE=0, interrupts disabled ME=0, machine check interrupt disabled CE=0, critical interrupts disabled GS=1, guest state
R3	For boot CPUs will be effective address of the guest device tree image. For secondary CPUs will be value of R3 field in the ePAPR spin table.
R4	0
R5	0
R6	For boot CPUs: ePAPR magic value—0x45504150 For secondary CPUs: zero.
R7	Size of the boot or secondary IMA (see section Initial Mapped Areas on page 2156)
R8	0
R9	0
R10—R31	undefined
F0—F31	undefined (floating point registers)
TCR	WRC=0, no watchdog timer reset will occur WIE=0, watchdog timer interrupt disabled FIE=0, fixed interval timer disabled DIE=0, decrementer interrupt disabled
PIR	Contains the partition-relative CPU index for the current CPU.
other registers	Undefined
TLB	Has a mapping for the IMA as per the ePAPR. The initial mapping will be in TLB1. See Initial Mapped Areas on page 2156.

11.1.2.4.10.3.2 Secondary CPUs

At partition start, all secondary vcpus are in a quiescent state and spinning in the spin-table as per the ePAPR. They can be released from the spin by writing the location specified in the cpu-release-addr property as defined in the ePAPR.

The vcpu does not support a writeable PIR register and thus the pir field in the spin table is not supported.

11.1.2.4.10.4 State of Hypervisor Provided Services

All virtual interrupt sources have interrupts masked in the VMPIC.

11.1.2.4.10.5 State of Platform Hardware

The initial state of I/O devices is undefined, except that all hardware interrupt sources have interrupts masked in the VMPIC.

All DMA-capable devices have DMA disabled unless the no-dma-disable property is specified on a partition node or device node in the hypervisor configuration tree (see Partition Node Properties on page 2215 and Device Configuration Nodes on page 2222 for additional details).

11.1.2.4.11 Privileged Partitions

A partition can be designated as 'privileged' which grants it the ability to issue a platform reset hypercall. See Partition Node Properties on page 2215, for information on defining privileged partitions. See FH_SYSTEM_RESET on page 2186 for information on the FH_SYSTEM_RESET hcall.

11.1.2.5 ePAPR virtualization

11.1.2.5.1 ePAPR Virtualization Overview

The power.org Embedded Power Architecture Platform Requirements (ePAPR) defines virtualization standards including:

- Hypercall ABI
- Hypercall services
- Virtualization extensions to device tree, so that guest operating systems are aware of the resources and services offered by a hypervisor

11.1.2.5.2 Hypercall Application Binary Interface (ABI)

An explicit invocation of the hypervisor by a guest is called a hypercall or hcall. This is performed by executing an instruction that causes an exception, in much the same way as a Unix system call is performed. One argument is a token that designates the actual function to perform. The remaining arguments and their interpretation are specific to the function of the hcall.

The hcall function depends on a modified system call (LEVEL=1) instruction which traps directly to hypervisor mode in the processor.

Summary

- The hypercall number shall be contained in r11.
- Input parameters shall be contained in r3 through r10, inclusive.
- Hypercalls shall return a success code and place this value in r3.
- Further output parameters shall be contained in r4 through r11, inclusive.
- If more data must be transferred in either direction in a single hypercall, that data must be placed into memory, and that must be specified by the hypercall API (the ABI does not define this behavior).

Table 402. Register Volatility

Register	Description
r0	Volatile
r1–r2	Nonvolatile

Table continues on the next page...

Table 402. Register Volatility (continued)

Register	Description
r3	Volatile parameter and return value for status
r4–r10	Volatile input and output value
r11	Volatile hypercall Token and output value
r12	Volatile
r13–r31	Nonvolatile
LR	Nonvolatile
CTR	Volatile
XER	Volatile
CR2–CR4	Nonvolatile
Remaining CR fields	Volatile
Other Registers	Nonvolatile

Contents of registers that are considered "nonvolatile" shall be preserved across hypercalls.

11.1.2.5.3 ePAPR Hypercall Token Definition

The ePAPR hcall ABI specifies that an hcall token identifying the hcall be placed in r11. An hcall token is 32-bits and is defined as follows:

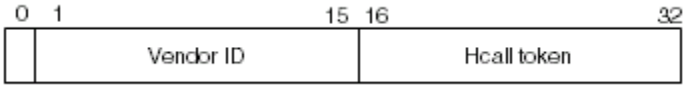

Figure 349. hcall token

Bit 0 (msb) is reserved and must be zero.

The vendor ID encoding is a 15-bit value defined as specified below:

Table 403. Vendor ID encoding

Vendor ID	Vendor Name
0	reserved for private, local use
1	ePAPR (hcall is defined by the ePAPR)
2	NXP Semiconductor

Table continues on the next page...

Table 403. Vendor ID encoding (continued)

Vendor ID	Vendor Name
3	International Business Machines
4	Green Hills Software
5	Enea
6	Wind River Systems
7	Applied Micro Circuits
42	KVM (Kernel Virtual Machine)

The ePAPR hcall tokens values are encoded as specified below.

Table 404. ePAPR Hypercall Token Definition

Hypercall Token Symbolic Name	Value
EV_BYTE_CHANNEL_SEND	1
EV_BYTE_CHANNEL_RECEIVE	2
EV_BYTE_CHANNEL_POLL	3
EV_INT_SET_CONFIG	4
EV_INT_GET_CONFIG	5
EV_INT_SET_MASK	6
EV_INT_GET_MASK	7
EV_INT_EOI	10
EV_DOORBELL_SEND	14

11.1.2.5.4 Hypercall Return Codes

Hypercalls return a status value in r3 encoded as follows:

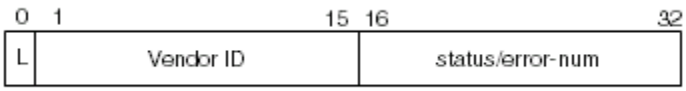

Figure 350. Hypercalls return

Vendor specific errors are encoded by setting the vendor ID (see ePAPR Hypercall Token Definition on page 2159).

Local/private errors that are not vendor specific can be encoded by setting the L bit.

The following tables defines the return codes that may be returned from hypercalls. A return code of zero indicates that the hypercall succeeded.

Table 405. ePAPR hcall return codes

Symbolic Name	Value	Meaning
	0	Success-- the operation completed successfully
EV_EPERM	1	Operation not permitted
EV_ENOENT	2	Entry Not Found
EV_EIO	3	I/O error occurred
EV_EAGAIN	4	The operation had insufficient resources to complete and should be retried
EV_ENOMEM	5	There was insufficient memory to complete the operation
EV_EFAULT	6	Bad guest address
EV_ENODEV	7	No such device
EV_EINVAL	8	An argument supplied to the hcall was out of range or invalid
EV_INTERNAL	9	An internal error occurred
EV_CONFIG	10	A configuration error was detected
EV_INVALID_STATE	11	The object is in an invalid state
EV_UNIMPLEMENTED	12	Unimplemented hypercall
EV_BUFFER_OVERFLOW	13	Caller-supplied buffer too small

11.1.2.5.5 ePAPR Hypervisor Node

Guest operating system can determine the virtualization resources available to them by looking at the **/hypervisor** node that will be present in the device tree passed to the guest operating system.

The name of the hypervisor node shall be "hypervisor" and it must be located at the root of the guest device tree.

The hypervisor node support the following properties:

Table 406. ePAPR hypervisor node

Property Name	Usage	Value Type	Definition
compatible	R	<string>	Must contain "epapr,hypervisor-<version#>" Where version# indicates the version of the ePAPR virtualization extensions that the hypervisor is compatible with.

Table continues on the next page...

Table 406. ePAPR hypervisor node (continued)

Property Name	Usage	Value Type	Definition
hcall-instructions	R	<prop-encoded-array>	Consists of up to 4 cells that specify a sequence of Power ISA instructions used in making a hypercall. Each cell contains a Power ISA opcode. Example: hcall-instructions = <0x44000022>; // sc level=1
guest-id	R	<u32>	A hypervisor provided guest identification number that is guaranteed to be unique across all partitions.
guest-name	R	<string>	A human readable string that describes the guest
has-idle	SD	<none>	If present, the hypervisor supports the EV_IDLE hcall
has-msgsnd-hcall	SD	<none>	If present, the hypervisor supports the EV_MSGSND hcall
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.5.6 ePAPR virtual interrupt controller services

In a virtualized implementation of the Power Architecture, interrupt controller services may be provided by a virtual interrupt controller accessed via a hypercall interface. The ePAPR "virtual interrupt controller" provides interrupt controller services for external interrupts.

External interrupts received by a partition can come from two sources:

- Hardware interrupts - hardware interrupts come from external interrupt lines or on-chip I/O devices
- Virtual interrupts - virtual interrupts are generated by the hypervisor as part of some hypervisor service or hypervisor-created virtual device.

Both types of interrupts are processed using the same programming model and same set of hcalls.

Each interrupt source in a partition has a partition-wide unique interrupt source number. Interrupt number 0 is reserved, and indicates a spurious interrupt (see the EV_INT_IACK hcall).

Table 407. Interrupt controller hcalls

Hypercall	Description
EV_INT_SET_CONFIG	Configures an interrupt
EV_INT_GET_CONFIG	Returns the configuration of an interrupt
EV_INT_SET_MASK	Sets the mask for an interrupt
EV_INT_GET_MASK	Returns the mask for an interrupt
EV_INT_EOI	Signals the end of processing for an interrupt

11.1.2.5.6.1 Virtual Interrupt Controller Device Tree Representation

11.1.2.5.6.1.1 Interrupt Controller Node

The ePAPR virtual interrupt controller is represented as a node in guest device trees with the properties as described in the table below:

Table 408. ePAPR virtual interrupt controller

Property Name	Usage	Value Type	Definition
compatible	R	<string>	Must contain "epapr,hv-pic".
hv-handle	O	<u32>	Specifies a handle to the interrupt controller. This handle may be used in hcalls that require an interrupt controller handle.
#interrupt-cells	R	<u32>	Must be 2
#address-cells	R	<u32>	Must be 0
interrupt-controller	R	<none>	Property must be present to indicate that this node is an interrupt controller
priority-count	R	<u32>	Defines the number of priorities supported by the virtual interrupt controller. The lowest priority (least-favored) is 0.
has-external-proxy	SD	<none>	If present, indicates that the hardware platform and virtual interrupt controller support the external proxy feature of the Power architecture.
no-priority	SD	<none>	If present indicates that the virtual interrupt controller does not implement the interrupt priority mechanism.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.5.6.1.2 Interrupt Specifiers

The *interrupts* property of interrupt children of the "epapr,hv-pic" node consists of two cells encoded as follows:

<interrupt-src-number flags>

Where:

- *interrupt-src-number* specifies the interrupt source number that may be used in the hcalls to configure and manage the interrupt source
- *flags* describes the level-sense encoding of the interrupt, encoded as:

Table 409. epapr,hv-pic interrupt specifier flags encoding

Bits	Description
31	Polarity 0 Polarity is active-low or negative edge triggered. 1 Polarity is active-high or positive edge-triggered.

Table continues on the next page...

Table 409. epapr,hv-pic interrupt specifier flags encoding (continued)

Bits	Description
30	Sense 0 The interrupt is edge sensitive 1 The interrupt is level sensitive

11.1.2.5.6.2 ePAPR interrupt controller hypercalls

11.1.2.5.6.2.1 EV_INT_SET_CONFIG

Hypercall: EV_INT_SET_CONFIG

Description: Configures the priority, destination CPU, and level/sense for an interrupt source

Arguments:

Table 410. EV_INT_SET_CONFIG Arguments

r11	hcall-token	EV_INT_SET_CONFIG
r3	interrupt	Interrupt source number (from the interrupt specifier)
r4	config	Specifies the configuration of the interrupt source. The config value is encoded as described in Interrupt Specifiers on page 2163.
r5	priority	Priority. Specifies the interrupt priority. The allowable range of priorities (lowest to highest) is described by the "priority-count" property on the "epapr,hv-pic" node. A priority value of 0 inhibits signaling of this interrupt.
r6	destination	Destination CPU. A number that identifies which CPU/thread receives the interrupt. This value matches the device tree "reg" property corresponding to the CPU/thread.

Return values:

Table 411. EV_INT_GET_CONFIG return values

r3	Status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : a parameter was out of range or invalid

11.1.2.5.6.2.2 EV_INT_GET_CONFIG

Hypercall: EV_INT_GET_CONFIG

Description: Returns the configuration of the specified interrupt

Arguments:

Table 412. EV_INT_GET_CONFIG Arguments

r11	hcall-token	EV_INT_GET_CONFIG

Table continues on the next page...

Table 412. EV_INT_GET_CONFIG Arguments (continued)

r3	Interrupt	Interrupt source number (from the interrupt specifier)

Return values:

Table 413. EV_INT_GET_CONFIG return values

r3	Status	Status of the hypercall 0: the operation completed successfully EV_EINVAL : the interrupt number was invalid
r4	config	Interrupt configuration. See Interrupt Specifiers on page 2163 for a description of the bit encoding of this value.
r5	priority	Priority. Specifies the interrupt priority. The allowable range of priorities (lowest to highest) is described by the "priority-count" property on the "epapr,hv-pic" node. A priority value of 0 inhibits signaling of this interrupt.
r6	destination	Destination CPU. A number that identifies which CPU/thread receives the interrupt. This value matches the device tree "reg" property corresponding to the CPU/thread.

11.1.2.5.6.2.3 EV_INT_SET_MASK

Hypercall: EV_INT_SET_MASK

Description: Sets the mask for the specified interrupt source

Arguments:

Table 414. EV_INT_SET_MASK Arguments

r11	hcall-token	EV_INT_SET_MASK
r3	interrupt	Interrupt source number (from the interrupt specifier)
r4	mask	Specifies whether the interrupt source is masked Zero: This interrupt source is enabled nonzero: This interrupt source is disabled

Return values:

Table 415. EV_INT_SET_MASK return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the interrupt number was invalid

11.1.2.5.6.2.4 EV_INT_GET_MASK

Hypercall: EV_INT_GET_MASK

Description: Returns the mask for the specified interrupt source

Arguments:

Table 416. EV_INT_GET_MASK Arguments

r11	hcall-token	EV_INT_GET_MASK
r3	interrupt	Interrupt source number (from the interrupt specifier)

Return values:

Table 417. EV_INT_GET_MASK return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the interrupt number was invalid
r4	mask	Specifies whether the interrupt source is masked Zero: This interrupt source is enabled nonzero: This interrupt source is disabled

11.1.2.5.6.2.5 EV_INT_EOI

Hypercall: EV_INT_EOI

Description: Signals the end of processing for the specified interrupt, which must be the highest priority interrupt currently in service.

An "in service" interrupt is one that has been acknowledged—either explicitly via EV_INT_IACK or by hardware that supports Power Architecture Category: External Proxy.

Arguments:

Table 418. EV_INT_EOI Arguments

r11	hcall-token	FH_VMPIC_ EOI
r3	interrupt	Interrupt source number (from the interrupt specifier)

Return values:

Table 419. EV_INT_EOI return values

r3	status	Status of the hypercall 0 the operation completed successfully EV_INTERNAL-an error occurred

NOTE

It is the responsibility of guest software to ensure that the interrupt source specified in this hcall is the highest priority interrupt in service.

11.1.2.5.7 Byte-channel Services

11.1.2.5.7.1 Byte-channel Services Overview

A byte-channel is a hypercall-based, interrupt-driven character-based I/O channel (similar to a UART). Hypercalls are available to send, receive, and poll a channel.

Table 420. hcalls for Byte-Channel Services

Hypercall	Description
EV_BYTE_CHANNEL_SEND	Sends data to a byte-channel.
EV_BYTE_CHANNEL_RECEIVE	Receives bytes of data from a byte-channel.
EV_BYTE_CHANNEL_POLL	Returns the status of the byte-channel send and receive buffers

11.1.2.5.7.2 Byte-channel Services Guest Device Tree Representation

Byte-channels are specified in the guest device tree as follows:

Table 421. Guest Device Tree

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "epapr,hv-byte-channel"
hv-handle	R	<u32>	Specifies the handle to the byte-channel. This value must be used by guest software for all byte-channel related hypercalls.
interrupts	R	<prop-encoded-array	Must consist of one or two interrupt specifiers encoded as follows: <rx-interrupt-specifier [tx-interrupt-specifier]> If only one interrupt specifier is present, then the implementation does not support TX interrupts. The virtual device shall generate a receive interrupt (RX) after an increase in the number of bytes available in the byte-channel's receive buffer. If implemented, the virtual device shall generate a transmit interrupt (TX) after an increase in the space available in the byte-channel's transmit buffer. Both TX and RX interrupts shall be edge-triggered.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.5.7.3 Byte-channel Hypercalls

The byte-channel hypercalls are nonblocking and synchronous. All hypercalls perform the requested task and return. There are no asynchronous side effects. If the request could not be completed (e.g. no space, no data) the return code of the hypercall indicates the reason the call did not complete.

11.1.2.5.7.3.1 EV_BYTE_CHANNEL_SEND

Hypercall: EV_BYTE_CHANNEL_SEND

Description: Description: Sends data to a byte-channel. The maximum number of bytes that can be sent is 16.

Arguments:

Table 422. EV_BYTE_CHANNEL_SEND Arguments

r11	hcall-token	EV_BYTE_CHANNEL_SEND
r3	handle	Byte-channel handle
r4	count	has count of bytes available in r5, r6, r7, and r8
r5,r6,r7,r8	byte string	The byte string starts in register r5 and proceeds toward the low order byte in register r8 for the number of characters specified in r4. The contents of all other byte locations of registers r5-r8 are undefined. Each register holds at most 4 bytes, which means on 64-bit CPUs only the low order 4 bytes of the registers are defined.

Return values:

Table 423. EV_BYTE_CHANNEL_SEND return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL: Invalid parameter EV_EAGAIN: The byte-channel buffer did not have sufficient space and no characters were sent. The operation should be retried at a later time.
r4	count	Count of characters sent.

11.1.2.5.7.3.2 EV_BYTE_CHANNEL_RECEIVE

Hypercall: EV_BYTE_CHANNEL_RECEIVE

Description: Receives bytes of data from a byte-channel. The maximum number of bytes received is 16.

Arguments:

Table 424. EV_BYTE_CHANNEL_RECEIVE Arguments

r11	hcall-token	EV_BYTE_CHANNEL_RECEIVE
r3	handle	Byte-channel handle
r4	max receive byte count	Specifies the maximum number of characters to receive. This value can be no larger than 16.

Return values:

Table 425. EV_BYTE_CHANNEL_RECEIVE return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : a parameter was invalid
r4	count	Count of characters available in r5, r6, r7 and r8 A count of zero indicates no characters are available.
r5,r6,r7,r8	character string	The byte string starts in register r5 and proceeds toward the low order byte in register r8 for the number of characters specified in r4. The contents of all other byte locations of registers r5-r8 are undefined. Each register holds at most 4 bytes, which means on 64-bit CPUs only the low order 4 bytes of the registers are defined.

11.1.2.5.7.3.3 EV_BYTE_CHANNEL_POLL

Hypercall: EV_BYTE_CHANNEL_POLL

Description: returns the status of the byte-channel send and receive buffers

Arguments:

Table 426. EV_BYTE_CHANNEL_POLL Arguments

r11	hcall-token	EV_BYTE_CHANNEL_POLL
r3	handle	Byte-channel handle

Return values:

Table 427. EV_BYTE_CHANNEL_POLL return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : handle was invalid
r4	rx count	Count of bytes available in the byte-channel's receive buffer.
r5	tx count	Count of space available in the byte-channel's transmit buffer.

11.1.2.5.8 Inter-partition doorbells

11.1.2.5.8.1 Inter-partition Doorbells Overview

A doorbell is an inter-partition signaling mechanism. A doorbell allows one partition to cause an interrupt in one (or possibly more) target partitions. The doorbell results in an external interrupt in the destination partition (i.e. the interrupt is gated off of MSR[EE] and the exception handler specified in IVOR4 execute).

Note, doorbell interrupts may be coalesced—if multiple senders issue a doorbell to the same receive endpoint, the receiver may see only one interrupt. If a sender issues multiple doorbells to a receiver that has interrupts disabled the receiver may only see one interrupt.

A partition is aware of the doorbells available to it through its guest device tree which contains a node for each doorbell endpoint.

11.1.2.5.8.2 Doorbell Send Endpoints

Doorbell send endpoints are represented in a guest device tree with the following properties:

Table 428. Doorbell Send Endpoints

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "epapr,hv-doorbell-send-handle"
hv-handle	R	<u32>	Specifies the handle to the doorbell. This value must be used by guest software for doorbell related hypercalls.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.5.8.3 Doorbell Receive Endpoints

Doorbell receive endpoints are represented in a guest device tree with the following properties:

Table 429. Doorbell Receive Endpoints

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "epapr,hv-doorbell-receive-handle"
interrupts	R	<prop-encoded-array	Must consist of one interrupt specifier.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.5.8.4 Doorbell Hypercall

Hypercall: EV_DOORBELL_SEND

Description: Sends a doorbell signal to a partition. This causes an external interrupt in the destination partition.

Arguments:

Table 430. EV_DOORBELL_SEND Arguments

r11	hcall-token	EV_DOORBELL_SEND
r3	handle	Specifies the doorbell handle of the partition to signal. This handle comes from the device tree.

Return values:

Table 431. EV_DOORBELL_SEND return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : handle was invalid EV_CONFIG: there was a configuration error with the doorbell

11.1.2.6 NXP hypervisor services

In additional to the ePAPR hypercall services, the hypervisor provides additional services described in this chapter.

11.1.2.6.1 NXP Hypervisor Services Overview

All NXP hypercalls follow the ePAPR hypercall ABI (see Hypercall Application Binary Interface (ABI) on page 2158).

11.1.2.6.2 NXP Hypercall Token Definition

The NXP hcall tokens values are encoded.

Table 432. NXP Hypercall Token Definition

Hypercall Token Symbolic Name	Value
FH_ERR_GET_INFO	1
FH_PARTITION_GET_DTPROP	2
FH_PARTITION_SET_DTPROP	3
FH_PARTITION_RESTART	4
FH_PARTITION_GET_STATUS	5
FH_PARTITION_START	6
FH_PARTITION_STOP	7
FH_PARTITION_MEMCPY	8
FH_DMA_ENABLE	9
FH_DMA_DISABLE	10
FH_SEND_NMI	11
FH_VMPIC_GET_MSIR	12
FH_SYSTEM_RESET	13
FH_GET_CORE_STATE	14
FH_ENTER_NAP	15
FH_EXIT_NAP	16
FH_CLAIM_DEVICE	17

11.1.2.6.3 Interrupt Controller Services

The ePAPR interrupt controller services (see ePAPR Hypervisor Node on page 2161) are used for managing interrupt sources. This section describes additional services and extensions to the ePAPR PIC services.

11.1.2.6.3.1 Interrupt Processing

Interrupts should be initialized and processed by guest software as follows:

- Guest software configures the vector number, priority, polarity, sense, and destination CPU of an interrupt source with the EV_INT_SET_CONFIG hypercall
- Interrupt sources can be masked and unmasked at the virtual interrupt controller with the EV_INT_SET_MASK hypercall
- To process a pending external interrupt:
  - The guest's interrupt service routine reads the processor core's EPR (external proxy register) to get the interrupt number of the pending interrupt. The EPR must be read before enabling interrupts (MSR[EE]).
  - When interrupt processing is complete the guest issues a EV_INT_EOI- this signals the end of processing for the highest-priority interrupt currently in service.

NOTE

Hardware interrupt sources cannot be configured while an interrupt is active.

11.1.2.6.3.2 Message Signaled Interrupt Processing

When a PCI Express message signaled interrupt occurs, an additional step is necessary in addition to those described in Interrupt Processing on page 2172 in processing the interrupt. Each MSI interrupt may be caused by one of 32 sources and this is indicated in the corresponding MPIC MSIR. This register can be read using the FH_VMPIC_GET_MSIR hcall.

11.1.2.6.3.3 Interrupt Priority

NOTE

The hypervisor does not support an ePAPR-compliant priority mechanism. The interrupt controller node specifies *no-priority* and does not specify a priority count.

All virtual interrupts (e.g. byte-channels, inter-partition doorbells, partition management interrupts) have the same priority and are sent to partitions in the order that they are received.

Hardware interrupt sources can be individually configured with priorities from 0 (least favored) to 15 (most favored) with the EV_INT_SET_CONFIG hypercall.

Given several concurrent incoming interrupts, the highest priority interrupt is asserted if the following apply:

The interrupt is not masked.

The priority of the interrupt is higher than any other interrupts in service.

11.1.2.6.3.4 Interrupt Controller Node in the Guest Device Tree

The table below defines additions to the ePAPR interrupt controller node representation (see Byte-channel Services Overview on page 2167).

VMPIC is represented in guest device trees with a device node name "vmpic" and properties as described below.

Table 433. VMPIC Representation

Property Name	Usage	Value Type	Definition
compatible	SD	<string>	If direct EOI is enabled for this partition (see section FH_VMPIC_GET_MSIR on page 2173) the compatible will include the value "fsl,hv-mpic-per-cpu".

Table continues on the next page...

Table 433. VMPIC Representation (continued)

Property Name	Usage	Value Type	Definition
reg	O	<prop-encoded-array>	A standard property. This property will only be present if direct EOI is enabled for this partition (see section FH_VMPIC_GET_MSIR on page 2173). If present contains the guest physical address and size of the per-CPU MPIC registers.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.6.3.5 ePAPR Interrupt Specifiers

Interrupt specifiers follow the ePAPR with an additional bit in the flags field specifying whether direct EOI may be used.

Table 434. Interrupt specifier flags encoding

Bits	Description
31	Polarity 0 Polarity is active-low or negative edge triggered. 1 Polarity is active-high or positive edge-triggered.
30	Sense 0 The interrupt is edge sensitive 1 The interrupt is level sensitive
29	MPIC direct 0 Direct EOI may not be used in the processing of this interrupt. 1 Direct EOI may be used in the processing of this interrupt

11.1.2.6.3.6 MSI Representation in the Guest Device Tree

An MSI node is identical to that of the hardware device tree except for the following:

- The *compatible* property string is "fsl,hv-mpic-msi"

The *reg property* is not present. This is because the MSI block is not accessible directly via loads and stores.

11.1.2.6.3.7 FH_VMPIC_GET_MSIR

Hypercall: FH_VMPIC_ GET_MSIR

Description: Description: Gets the MPIC MSIRx (Shared Message Signaled Interrupt Register) associated with the specified interrupt.

Arguments:

Table 435. FH_VMPIC_ GET_MSIR Arguments

r11	hcall-token	FH_VMPIC_GET_MSIR

Table continues on the next page...

Table 435. FH_VMPIC_ GET_MSIR Arguments (continued)

r3	interrupt	Interrupt number (from guest device tree) of the interrupt source for which to get the MSI interrupt status.

Return values:

Table 436. FH_VMPIC_ GET_MSIR return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the interrupt handle was not for an MSI interrupt
r4	msir value	Contains the MSIRxx value for the specified interrupt

C API:

Table 437. FH_VMPIC_ GET_MSIR C API

unsigned int fh_vmpic_get_msir (*unsigned int* interrupt, unsigned int *msir_val)

11.1.2.6.3.8 Non Maskable Interrupts

An hcall mechanism is available that enables one CPU to send a non-maskable interrupt to other CPUs within the same partition. See the FH_SEND_NMI hcall (FH_SEND_NMI on page 2185).

The interrupt cannot be masked via the MSR and appears on the target CPUs as a machine check with MCSR[NMI] set.

11.1.2.6.3.9 Direct EOI

The hypervisor provides a mechanism by which in some circumstances an end-of-interrupt can be performed with no hypercall. When the *mpic-direct-eoi* property is specified in on the node defining a partition, the guest OS will be granted direct access to the per-CPU registers in the MPIC registers (see the *P4080 QorIQ Integrated Host Processor Reference Manual*), which enables the guest to perform direct EOIs.

Enabling direct EOI for a partition has some important considerations and restrictions.

Restrictions

- Direct EOI is only supported for hardware interrupts sources directly managed by the hardware MPIC in the SOC
- EOI for all other interrupt source, such as virtual interrupts (e.g. doorbells, byte-channels), must be done with the FH_VMPIC_EOI hcall. MPIC managed interrupts can be distinguished in the interrupt specifier for the interrupt (see Interrupt Controller Node in the Guest Device Tree on page 2172).

Considerations

- The partition and guest OS to which direct EOI is granted **must be trusted and well behaved**. The MPIC registers which are being granted contain PIC registers beside the EOI register which should not be accessed by the guest.
- Direct EOI will not be compatible with any future implementations of the hypervisor that support multiple operating systems per physical CPU.

To enable direct EOI, specify the mpic-direct-eoi property in the hypervisor configuration tree on the partition node specifying the partition (see Partition Node Properties on page 2215).

With direct EOI enabled, the vmpic node in the guest device tree will have a mpic-reg property and a compatible string that includes "fsl,hv-mpic-per-cpu" (see Interrupt Controller Node in the Guest Device Tree on page 2172).

11.1.2.6.4 Inter-partition doorbell services

In addition to the standard ePAPR inter-partition doorbells, the NXP hypervisor supports several fast doorbells with the same interface.

11.1.2.6.4.1 Fast Doorbells

The hypervisor supports up to four 'fast' doorbells. These are doorbells that use a different hardware mechanism which provides lower latency compared to regular doorbells. In addition, the direct EOI mechanism (see Direct EOI on page 2174) is supported for fast doorbells.

See Global Doorbell Definition on page 2213, for information on defining fast doorbells.

The send and receive endpoints are identical to regular doorbell.

NOTE

Due the underlying hardware mechanism used to implement fast doorbells, the ability to mask/unmask fast doorbells interrupts with the interrupt controllers services is limited. Masking the receive interrupt for any receive endpoint will mask all receive endpoints for that doorbell. It is recommended that doorbells not be masked at the interrupt controller.

11.1.2.6.5 Partition management

11.1.2.6.5.1 Partition Management Overview

The hypervisor architecture supports the concept of a manager partition. A manager partition has the capability to start, stop, and restart other partitions using hcalls. For partitions in the stopped state a manager partition can copy data to and from the managed partition, thus enabling the manager to load OS images, etc into the managed partition.

11.1.2.6.5.2 Partition Handles

Partitions are managed via handles. A manager partition will have a partition management node in its device tree for each partition it manages. The reg property in the partition management node defines the handle used in partition management hcalls.

Partitions can perform partition related hcalls on themselves using the special interrupt handle value of -1.

11.1.2.6.5.3 Partition Management Interrupts

A manager partition may get doorbell interrupts related to managed partitions. Three types of interrupts may be generated:

- Notification on managed partition state changes
  - Transition from *starting* to *running*
  - Transition from *stopping* to *stopped*
  - Transition from *pausing* to *paused*
  - Transition from *resuming* to *running*
- Notification on managed partition watchdog expiration
- Notification on managed partition restart request

The partition management node has 3 doorbell node children that define these interrupt sources.

In addition, a special doorbell is defined that enables a manager partition to signal a managed partition to do a clean shutdown. The manager has a send doorbell endpoint and the managed partition has a receive doorbell endpoint.

See Partition Management Guest Device Tree Representation on page 2176for details regarding these send and receive doorbell interrupts for partition management.

11.1.2.6.5.4 Partition Status

A manager partition can read the status of a managed partition using the FH_PARTITION_GET_STATUS hcall.

11.1.2.6.5.5 Partition Management Guest Device Tree Representation

Partitions are managed via handles. Each managed partition has a partition management node under the *handles* node in the manager partition's guest device tree. The node specifies a handle to the partition used by management related hypercalls. In addition, each partition management node contains 4 child nodes that represent 3 receive doorbell endpoints for the partition management interrupts that the manager may receive and 1send doorbell endpoint to request a clean shutdown by the managed partition.

The three receive doorbells are as follows:

- Managed partition state change—signaled when the managed partition moves between the *stopped* and *running* states
- Managed partition watchdog expiration—signaled when the managed partition has a watchdog expiration event
- Managed partition restart request—signaled when the managed partition has made a reboot request to the hypervisor, and the hypervisor does not have a client program image to load

The partition management node for the managed partition will have the properties in the table below:

Table 438. Guest Device Tree Partition Management Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must contain "fsl,hv-partition-handle"
reg	R	<u32>	Specifies the handle to the partition
label	R	<string>	Identical to the label property on the partition node in the hypervisor configuration tree describing the managed partition.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

A managed partition state change doorbell node is a child of the partition management node and has the following properties:

Table 439. Managed Partition State Change Doorbell Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must contain 2 strings—"fsl,hv-state-change-doorbell," "fsl,hv-doorbell-receive-handle"
interrupts	R	<prop-encoded-array>	Consists of one interrupt specifier.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

A managed partition watchdog expiration doorbell node is a child of the partition management node and has the following properties:

Table 440. Managed Partition Watchdog Expiration Doorbell Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must contain 2 strings—"fsl,hv-watchdog-expiration-doorbell," "fsl,hv-doorbell-receive-handle"
interrupts	R	<prop-encoded-array	Consists of one interrupt specifier.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

managed partition restart request doorbell node is a child of the partition management node and has the following properties:

Table 441. Managed Partition Restart Request Doorbell Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must contain 2 strings—"fsl,hv-reset-request-doorbell," "fsl,hv-doorbell-receive-handle"
interrupts	R	<prop-encoded-array	Consists of one interrupt specifier.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

managed partition shutdown request doorbell node is a child of the partition management node and has the following properties:

Table 442. Managed Partition Shutdown Request Doorbell Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must contain 2 strings—"fsl,hv-shutdown-request-doorbell," "fsl,hv-doorbell-send-handle"
reg	R	<u32>	Specifies the handle to the doorbell.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.6.5.6 Partition management hypercalls

The hypervisor API specifies a set of hcalls to be used by a manager partition to manage partitions.

Table 443. Partition management hcalls

Hypercall	Description
FH_PARTITION_START	Boots and starts execution of the specified partition.
FH_PARTITION_STOP	Stops a partition.

Table continues on the next page...

Table 443. Partition management hcalls (continued)

Hypercall	Description
FH_PARTITION_RESTART	Requests that the current partition be reinitialized and restarted.
FH_PARTITION_GET_ STATUS	Gets the status of a partition.
FH_PARTITION_MEMCPY	Copies data to/from another partition's memory.
FH_PARTITION_GET_DTPROP	Gets a guest device tree property from the specified partition
FH_PARTITION_SET_DTPROP	Sets a guest device tree property in the specified partition
FH_PARTITION_STOP_DMA	Disables DMA for devices in the specified partition

11.1.2.6.5.6.1 FH_PARTITION_START

Hypercall: FH_PARTITION_START

Description: Boots and starts the execution of the specified partition. Partitions with a status of "running" may not be started.

This hypercall starts the partition's boot CPU core only. Partitions with multiple cores release their secondary cores as they wish using the secondary core spin table as defined by the ePAPR.

Arguments:

Table 444. FH_PARTITION_START Arguments

r11	hcall-token	FH_PARTITION_START
r3	partition- handle	specifies the handle of the partition to start
r4	entry-point	specifies the offset into the partition's initial mapped area (IMA) where the operating system entry point is located
r5	load	If non-zero, specifies that any hypervisor loaded images should be loaded prior to starting the partition.

Return values:

Table 445. FH_PARTITION_START return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the handle was invalid EV_INVALID_STATE : the targeted partition was not in the "stopped" state

C API:

Table 446. FH_PARTITION_START C API

unsigned int **fh_partition_start** (*int* **partition**, *uint32_t* **entry_point**, *int* **load**)

11.1.2.6.5.6.2 FH_PARTITION_STOP

Hypercall: FH_PARTITION_STOP

Description: Halts the execution of a running partition.

Arguments:

Table 447. FH_PARTITION_STOP Arguments

r11	hcall-token	FH_PARTITION_STOP
r3	partition- handle	Specifies the handle of the partition to stop. A value of -1 indicates the *current* partition-this results in the partition exiting and moving into the stopped state.

Return values:

Table 448. FH_PARTITION_STOP return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the handle was invalid EV_INVALID_STATE : the targeted partition was not in the "running" state

C API:

Table 449. FH_PARTITION_STOP C API

unsigned int **fh_partition_stop** (*int* **partition**)

11.1.2.6.5.6.3 FH_PARTITION_RESTART

Hypercall: FH_PARTITION_RESTART

Description: Requests that a partition be stopped and restarted.

Arguments:

Table 450. FH_PARTITION_RESTART Arguments

r11	hcall-token	FH_PARTITION_RESTART
r3	partition-handle	Specifies the handle of the partition to restart. A value of -1 indicates the *current* partition.

Return values:

FH_PARTITION_RESTART return values

r3	status	Status of the hypercall 0 : success-the request to restart was successful EV_EINVAL : the handle was invalid EV_INVALID_STATE : the targeted partition was not in the "running" state

C API:

Table 451. FH_PARTITION_RESTART C API

unsigned int **fh_partition_restart** (*int* **partition**)

NOTE

For a restart of the current partition this hcall never returns.

11.1.2.6.5.7 FH_PARTITION_GET_STATUS

Hypercall: FH_PARTITION_GET_STATUS

Description: Gets the status of a partition.

Arguments:

Table 452. FH_PARTITION_GET_STATUS Arguments

r11	hcall-token	FH_PARTITION_GET_STATUS
r3	partition handle	specifies the id of the partition for which the status should be read

Return values:

Table 453. FH_PARTITION_GET_STATUS return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL: the supplied handle was not valid
r4	partition status	Status of the partition 0 : stopped 1 : running 2 : starting 3 : stopping 4 : pausing 5 : paused 6 : resuming

C API:

Table 454. FH_PARTITION_GET_STATUS C API

unsigned int fh_partition_get_status (*int* partition, *unsigned int* * status)

11.1.2.6.5.7.1 FH_PARTITION_MEMCPY

Hypercall: FH_PARTITION_MEMCPY

Description: Copies data between the current ("*local*") partition and another ("*remote*") partition's memory. The physical addresses of the source and destination memory and the amount of data to copy are represented in a scatter gather list. Copying in either direction is supported—local-to-remote, or remote-to-local.

The scatter gather list consists of a variable-length array of struct fh_sg_list values. This structure must be guest physically contiguous. aligned on 32-byte boundary, so that no single structure can span two pages.

```
struct fh_sg_list {
        uint64_t source;      // guest physical address to copy from
        uint64_t destination; // guest physical address to copy to
        uint64_t size;        // number of bytes to copy
        uint64_t reserved;    // reserved, must be zero
}
```

The physical addresses specified must be valid guest physical addresses within the respective partition—the destination physical address must be valid in the destination partition (and may not be valid in the source partition).

Arguments:

Table 455. FH_PARTITION_MEMCPY Arguments

r11	hcall-token	FH_PARTITION_MEMCPY
r3	source-partition-handle	Specifies the handle of the source partition. A value of -1 indicates the *local* partition, otherwise the value is the handle of the *remote* partition.
r4	destination-partition-handle	Specifies the handle of the destination partition. A value of -1 indicates the *local* partition, otherwise the value is the handle of the *remote* partition.
r5	sg-list-high	Specifies the high-order 32-bits of the physical address of a scatter gather list that describes the entire data block being copied.
r6	sg-list-low	Specifies the low-order 32-bits of the physical address of a scatter gather list that describes the entire image being loaded. See definition of *sg-list-high* for a definition of the scatter gather list.
r7	count	A count of the number of items in the scatter gather list

Return values:

Table 456. FH_PARTITION_MEMCPY return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : a parameter was invalid EV_EFAULT - bad guest address

C API:

Table 457. FH_PARTITION_MEMCPY C API

unsigned int **fh_partition_memcpy** (*int* **source**, *int* **target**, *phys_addr_t* **sg_list** *, unsigned int* **count** *)*

11.1.2.6.5.7.2 FH_PARTITION_SET_DTPROP

Hypercall: FH_PARTITION_SET_DTPROP

Description: Sets the value of a property for the specified node in the guest device tree. This call is not permitted on partitions in the "starting" state. The address arguments are guest physical addresses and must point to data that is within a physically contiguous region of memory.

If the specified property does not exist, it will be created. If the property does exist, it will be replaced.

Arguments:

Table 458. FH_PARTITION_SET_DTPROP Arguments

r11	hcall-token	FH_PARTITION_SET_DTPROP
r3	partition-handle	specifies the handle of the partition
r4	dtpath-addr-hi	specifies the high order 32-bits of the guest physical address of the null-terminated string containing the full path to the node to update
r5	dtpath-addr-lo	specifies the low order 32-bits of the guest physical address of the null-terminated string containing the full path to the node to update
r6	propname-addr-hi	specifies the high order 32-bits of the guest physical address of the null-terminated string containing the name of the property to update
r7	propname-addr-lo	specifies the low order 32-bits of the guest physical address of the null-terminated string containing the name of the property to update
r8	propvalue-addr-hi	specifies the high order 32-bits of the guest physical address of the value to set in the property
r9	propvalue-addr-lo	specifies the low order 32-bits of the guest physical address of the value to set in the property
r10	propvalue-length	length (in bytes) of the property value

Return values:

Table 459. FH_PARTITION_SET_DTPROP return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : a parameter was invalid EV_ENOMEM - no memory to expand device tree EV_EFAULT - bad guest address EV_ENOENT - path or property not found EV_INVALID_STATE - the target partition was not in the 'stopped' state

C API:

Table 460. FH_PARTITION_SET_DTPROP C API

```
unsigned int fh_partition_dtprop_set(int handle,
uint64_t dtpath_addr,
uint64_t propname_addr,
uint64_t propvalue_addr,
uint32_t propvalue_len);
```

11.1.2.6.5.7.3 FH_PARTITION_GET_DTPROP

Hypercall: FH_PARTITION_GET_DTPROP

Description: Gets the value of a property for the specified node in the guest device tree. This call is not permitted on partitions in the "starting" state. The address arguments are guest physical addresses and must point to data that is within a physically contiguous region.

Arguments:

Table 461. FH_PARTITION_GET_DTPROP Arguments

r11	hcall-token	FH_PARTITION_GET_DTPROP
r3	partition-handle	specifies the handle of the partition
r4	dtpath-addr-hi	specifies the high order 32-bits of the guest physical address of the null-terminated string containing the full path to the node
r5	dtpath-addr-lo	specifies the low order 32-bits of the guest physical address of the null-terminated string containing the full path to the node
r6	propname-addr-hi	specifies the high order 32-bits of the guest physical address of the null-terminated string containing the name of the property to get
r7	propname-addr-lo	specifies the low order 32-bits of the guest physical address of the null-terminated string containing the name of the property to get

Table continues on the next page...

Table 461. FH_PARTITION_GET_DTPROP Arguments (continued)

r8	propvalue-addr-hi	specifies the high order 32-bits of the guest physical address of the location to store the property value.
r9	propvalue-addr-lo	specifies the low order 32-bits of the guest physical address of the location to store the property value
r10	propvalue-length	maximum length (in bytes) of the property value

Return values:

Table 462. FH_PARTITION_GET_DTPROP return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : a parameter was invalid EV_ENOMEM - no memory to expand device tree EV_EFAULT - bad guest address EV_INVALID_STATE - the target partition was not in the 'stopped' state
r4	propvalue-length	actual length (in bytes) of the property value returned

C API:

Table 463. FH_PARTITION_GET_DTPROP C API

```
unsigned int fh_partition_dtprop_get(int handle,
uint64_t dtpath_addr,
uint64_t propname_addr,
uint64_t propvalue_addr,
uint32_t *propvalue_len);
```

11.1.2.6.5.7.4 FH_PARTITION_STOP_DMA

Hypercall: FH_PARTITION_STOP_DMA

Description: Disables DMA for all devices in the managed partition.

Some partition configurations may specify that events such as a watchdog timeout should stop a partition. Normally when a partition moves into the stopped state DMA is stopped. However, there are use cases where it may be required to have DMA continue while a partition is stopped and subsequently restarted. The *defer-dma-disable* property (see Partition Node Properties on page 2215) specifies this behavior. If the disabling of DMA is deferred, it can explicitly stopped with the FH_PARTITION_STOP_DMA hcall. FH_PARTITION_STOP_DMA gives control of when DMA is stopped to the manager partition.

Deferring the disabling of DMA enables the manager partition to check the state and error status of the target partition prior to shutting off DMA, as the disabling of DMA in the target partition may generate additional errors from I/O devices belonging to the partition that may still be active.

The target partition must be in the *stopped* state.

Arguments:

Table 464. FH_PARTITION_STOP_DMA Arguments

r11	hcall-token	FH_PARTITION_STOP_DMA
r3	partition-handle	specifies the handle of the target partition

Return values:

Table 465. FH_PARTITION_STOP_DMA return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_INVALID_STATE : the target partition was not stopped EV_EINVAL: handle was invalid

C API:

Table 466. FH_PARTITION_STOP_DMA C API

unsigned int **fh_partition_stop_dma** (*unsigned int* **partition-handle**)

11.1.2.6.6 General services

The hypervisor API specifies a set of hcalls to provide general services. The hcalls are summarized below.

Table 467. General services hypercalls

Hypercall	Description
FH_SEND_NMI	Sends a non-maskable interrupt to the selected CPUs (within the current partition)
FH_SYSTEM_RESET	Requests a hardware reset of the system

11.1.2.6.6.1 FH_SEND_NMI

Hypercall: FH_SEND_NMI

Description: Sends a non-maskable interrupt to the selected CPUs within the current partition..

The interrupt cannot be masked via the MSR and appears on the target CPUs as a machine check with MCSR[NMI] set.

Arguments:

Table 468. FH_SEND_NMI Arguments

r11	hcall-token	FH_SEND_NMI
r3	vcpu-mask	mask specifying which virtual CPUs should receive the NMI. The LSB (least significant bit) specifies vcpu 0.

Return values:

Table 469. FH_SEND_NMI return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL : the vcpu mask was not valid

C API:

Table 470. FH_SEND_NMI C API

unsigned int **fh_send_nmi** *(uint32_t* **vcpu_mask** *)*

11.1.2.6.6.2 FH_SYSTEM_RESET

Hypercall: FH_SYSTEM_RESET

Requests a hardware reset of the system. If successful the call does not return. This hcall is only supported in privileged partitions (see Privileged Partitions on page 2158).

Description:

Arguments:

Table 471. FH_SYSTEM_RESET Arguments

r11	hcall-token	FH_SYSTEM_RESET

Return values:

Table 472. FH_SYSTEM_RESET return values

r3	status	Status of the hypercall EV_EPERM—operation not permitted (partition was not privileged). EV_ENODEV—don't know how to reset on this hardware EV_EIO—reset failed

C API:

Table 473. FH_SYSTEM_RESET C API

unsigned int **fh_system_reset** *(void)*

11.1.2.6.7 IOMMU services

The NXP QorIQ platform contains an IOMMU (also known as a Peripheral Access Management Unit or PAMU) that provides a mechanism to control and authorize device-to-memory accesses. A PAMU provides authorization and translation services for I/O traffic entering the Host/Coherency Domain.

The hypervisor manages the PAMUs and provides services to partitions to configure access windows enabling DMA-capable devices to read and write system memory.

In the hypervisor configuration tree DMA *windows* can be defined which specify a set of address windows in terms of guest physical addresses (see DMA windows on page 2211). These *DMA window* objects define the allowable address ranges

that devices can access, and are then referenced by device nodes representing DMA-capable devices (see Device nodes on page 2222). Based on the hypervisor configuration tree, the hypervisor sets up the tables used by the PAMU hardware.

At partition initialization, DMA is enabled by default. Guest software can explicitly disable and enables DMA via the FH_DMA_ENABLE and FH_DMA_DISABLE hcall.

11.1.2.6.7.1 IOMMU Services Guest Device Tree Representation

DMA capable devices have one or more of the properties described below in their guest device trees.

Table 474. Guest Device Tree DMA Properties

Property Name	Usage	Value Type	Definition
fsl,hv-dma-handle	SD	<u32>	Value is an array of liodn handle used in making DMA enable/disable hcalls
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.6.7.2 IOMMU Hypercalls

The hypervisor API specifies two hcalls to enable and disable.

Table 475. IOMMU Hypercalls

Hypercall	Description
FH_DMA_ENABLE	Enables DMA for an I/O device.
FH_DMA_DISABLE	Disables DMA for an I/O device.

11.1.2.6.7.3 IOMMU Hypercall Interface

11.1.2.6.7.3.1 FH_DMA_ENABLE

Hypercall: FH_DMA_ENABLE

Description: Enables DMA for the specified device. Note: if the specified device already had DMA enabled the return value from this hcall will still indicate success.

Arguments:

Table 476. FH_DMA_ENABLE Arguments

r11	hcall-token	FH_DMA_ENABLE
r3	handle	Specifies the handle of the I/O device for which to enable DMA. Guest software determines this value from the "*fsl,hv-dma-handle*" property in the device node in the guest device tree.

Return values:

Table 477. FH_DMA_ENABLE return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_INTERNAL : an error occurred EV_EINVAL: the supplied LIODN was not valid

C API:

Table 478. FH_DMA_ENABLE C API

unsigned int **fh_dma_enable** (*unsigned int* **handle**)

11.1.2.6.7.3.2 FH_DMA_DISABLE

Hypercall: FH_DMA_DISABLE

Description: Disables DMA for the specified device. Note: if the specified device already had DMA enabled the return value from this hcall will still indicate success.

Arguments:

Table 479. FH_DMA_DISABLE Arguments

r11	hcall-token	FH_DMA_DISABLE
r3	handle	specifies the handle of the I/O device for which to disable DMA. Guest software determines this value from the "*fsl,hv-dma-handle*" property in the device node in the guest device tree.

Return values:

Table 480. FH_DMA_DISABLE return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_NTERNAL : an error occurred EV_EINVAL: the supplied LIODN was not valid

C API:

Table 481. FH_DMA_DISABLE C API

unsigned int **fh_dma_disable** (*unsigned int* **liodn**)

11.1.2.6.8 Error Management

11.1.2.6.8.1 Error Management Overview

The hypervisor provides an error management architecture to report and log hardware errors.

Several types of hardware errors may occur in a system:

1. **Guest-owned device errors** are errors caused by a partition-owned device that may assert an error condition. This type of error is specific to a particular device and should be handled by the device driver managing the device. The hypervisor routes error interrupts of this type to the partition owning the device and they appear as PIC-based interrupts to the partition. Error interrupts are represented in the partition's guest device tree as per the device tree binding for the device and are handled like any other device interrupt.
2. **Partition errors** are system errors that must be addressed by the partition responsible for causing the error. These errors are placed in a *guest event queue* for handling by the guest OS, and the partition is notified by a machine check interrupt. An example of this type of error is an IOMMU access violation where an incorrectly programmed device attempts to make an illegal DMA access. Partition errors also includes CPU machine check conditions (e.g. cache parity error) that occur while a guest operating system is running.
3. **System Errors** are errors that may be system-wide in scope and may be non-recoverable. These errors each have a configurable policy (see Error Policy Configuration on page 2233), with one option being to log the error in a *global event queue* for handling by a partition designated to be an "error manager".

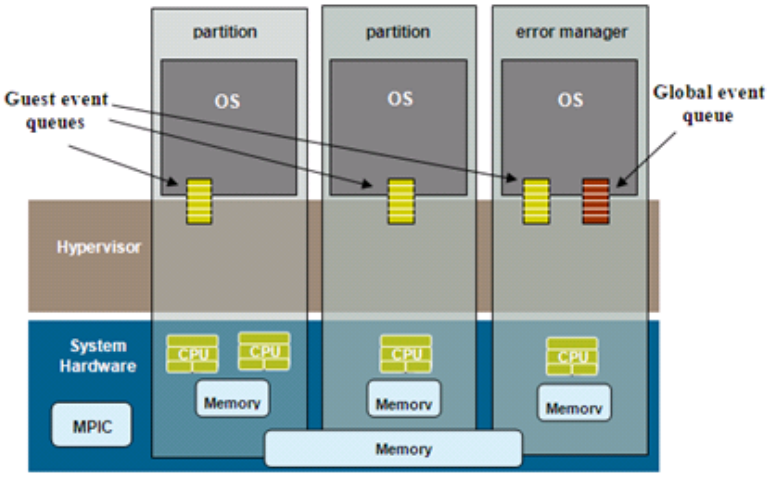

Figure 351. Global Event Queue

The error manager is designated by specifying the *error-manager* property on the partition node of the designated partition (see Partition Node Properties on page 2215).

The policy for each type of error can be configured in error configuration nodes in the hypervisor device tree. See Error Policy Configuration on page 2233.

11.1.2.6.8.2 Event notification interrupts

Guests are notified of errors in the guest event queue via a machine check (MCSR[MCP], IVOR1).

The error manager is notified of errors in the global event queue via a critical interrupt (IVOR0).

To handle both types of interrupts, operating systems invoke the FH_ERR_GET_INFO hcall to get the error event information.

11.1.2.6.8.3 Error Management Guest Device Tree Representation

The guest event queue is represented by a child node of the /**hypervisor** node in the guest device tree. The guest event queue node is represented with the following properties:

Table 482. Guest Event Queue Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Will be the value "fsl,hv-guest-error-queue". Defines a node used for accessing the guest event queue.
reg	R	<u32>	Specifies a handle that can be used in the fh_err_get_info hcall.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

The global event queue is represented in the guest device tree of an error manager partition with the following properties:

Table 483. Global Event Queue Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Will be the value "fsl,hv-error-manager". Specifies that this partition is an error manager.
reg	R	<u32>	Specifies a handle that can be used in the fh_claim_device or fh_err_get_info hcalls.
fsl,hv-claimable	SD	<string>	Will be present if 2 partitions are sharing error management responsibilities in an active/standby configuration. Valid values are: "active" - The partition is the active error manager "standby" - The partition is the standby error manager
fsl,hv-error-manager-cpu	R	<u32>	The virtual CPU number that will get critical interrupts indicating data in the global event queue.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.6.8.4 Error Domains, Error Types, Error Policies

Partition errors and system errors are classified into different error domains. Each domain has a unique type of error structure that is returned. The *error domain strings* and *error type strings* identify the domain and specific error.

The string identifiers are used to configure error policies and identify the error when an error is returned.

Table 484. Error Domains

Error domain String	Description
"ccf"	CoreNet coherency fabric errors
"misc"	Miscellaneous errors
"cpc"	CoreNet platform cache errors

Table continues on the next page...

Table 484. Error Domains (continued)

Error domain String	Description
"pamu"	Errors associated with the Peripheral Management Access Unit (an IOMMU)
"ddr"	DDR memory controller errors
"machine check"	Recoverable or guest machine check

Table 485. Error Policies

Policy	Policy Description
disable	The error condition is to be suppressed. Hardware will be configured so that the error is disabled.
notify	Place an error event in the global event queue, clear the error condition, and continue.
halt	Upon detection of the error condition, dump current state to the debug console, disable interrupts, and halt the hypervisor. If the hypervisor watchdog is enabled this will ultimately result in a watchdog timeout.
system-reset	Assert HRESET to reset the system.

11.1.2.6.8.5 FH_ERR_GET_INFO

Hypercall: FH_ERR_GET_INFO

Description: Removes an error event from the specified event queue. The caller provides the address of a physically contiguous buffer where the structure is returned with the details of the error.

Arguments:

Table 486. FH_ERR_GET_INFO Arguments

r11	hcall-token	FH_ERR_GET_INFO
r3	handle	Value from the reg property from the fsl,hv-guest-error-queue or fsl,hv-error-manager properties in the guest device tree.
r4	buf-size	maximum size (in bytes) of the error buffer
r5	errbuf-addr-hi	specifies the high order 32-bits of the guest physical address of the location to store the error structure.
r6	errbuf-addr-lo	specifies the low order 32-bits of the guest physical address of the location to store the error structure.

Table continues on the next page...

Table 486. FH_ERR_GET_INFO Arguments (continued)

r7	peek	Specifies whether to remove the entry or not. Valid values are: 0 - remove the first event from the queue 1 - read, but don't remove the first event from the queue All other values are reserved. Note: if an event is not removed from the queue the related interrupt will be reasserted when the ISR returns.

Return values:

Table 487. FH_ERR_GET_INFO return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_ENOENT : the queue was empty EV_EINVAL: invalid parameter EV_EFAULT - bad guest address
r4	buf-size	actual length (in bytes) of the error struct returned at the specified address

C API:

Table 488. FH_ERR_GET_INFO C API

unsigned int **fh_get_err_info**(uint32_t queue_select, uint32_t buf_size, uint64_t error_buf, uint32_t peek)

11.1.2.6.8.5.1 Error Structure

Error information returned by FH_GET_ERR_INFO is returned in an error structure. A portion of the structure is common to all error types and each error domain has unique fields that are represented in a sub-structure.

The error domain structures are specified in following sections.

Common error struct fields:

```
typedef struct {
    char domain[32];
    char error[128];
    char hdev_tree_path[256];
    char gdev_tree_path[256];
    union {
        // error domain structs go here
    };
} hv_error_t;
```

The common fields are defined as follows

Table 489. Error Structure common fields

Fields	Definition
domain	A character string that defines the error domain. See Error Domains, Error Types, Error Policies on page 2190 for a list of domains.
error	A character string that defines the error. See PAMU error domain on page 2193 for a list of error types.
hdev_tree_path	A string that specifies the path in the hardware device tree to the node that caused the error.
gdev_tree_path	A string that specifies the path in the guest device tree to the node that caused the error.

11.1.2.6.8.6 PAMU error domain

The PAMU error domain represents error conditions related to the Peripheral Management Access Unit.

Table 490. Error Types

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Operation error	pamu	"operation"	An operation error occurred in PAMU. An unsupported ATM or OTM code was read, or bad data was read due to an error in some other block (e.g. DDR or CPC). This error may or may not be fatal to a system depending on the device that PAMU was attempting to authorize when the error occurred.	disable, notify, halt, system-reset	notify
Single bit ECC error	pamu	"single-bit ecc"	A single-bit ECC error occurred accessing the PAMUs internal cache. The *single-bit-ecc-threshold* property may be specified on the error configuration node to set the policy of how many single bit ECC errors are to be tolerated before an error is asserted by the hardware. See Error Policy Configuration on page 2233 . The default threshold is 8.	disable, notify, halt, system-reset	disable

Table continues on the next page...

Table 490. Error Types (continued)

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Multiple-bit ECC error	pamu	"multi-bit ecc"	A multi-bit ECC error occurred accessing the PAMUs internal cache. This error is recoverable-the PAMU reverts to reading main memory if there is a cache failure.	disable, notify, halt, system-reset	disable
Access violation	pamu	"access violation"	A device made an unauthorized DMA access. Further DMA from the device will be disabled and an explicit FH_DMA_ENABLE hcall must be used to re-enable DMA.	disable, notify	notify

A structure contained within the general error structure (see) defines fields related to PAMU error conditions.

PAMU error struct fields:

```
struct pamu_error{
        uint32_t lpid;
        uint64_t access_violation_addr;
        uint32_t avs1;
        uint32_t avs2;
        uint32_t liodn_handle;
        uint32_t eccctl;
        uint32_t eccdis;
        uint32_t eccinten;
        uint32_t eccdet;
        uint32_t eccattr;
        uint64_t eccaddr;
        uint64_t eccdata;
        uint32_t poes1;
        uint64_t poeaddr;
} pamu_error_t;
```

The PAMU domain fields are defined as follows:

Table 491. PAMU error fields

Fields	Definition	Errors for Which the Field is Valid
lpid	The Partition ID (LPID) of the partition that caused the error.	access violation
access_violation_addr	The address being accessed that caused the access violation	access violation

Table continues on the next page...

Table 491. PAMU error fields (continued)

Fields	Definition	Errors for Which the Field is Valid
avs1	The value in the *Access Violation Status 1* Register. See the processor hardware reference manual for the encoding of this field.	access violation
avs2	The value in the *Access Violation Status 2* Register. See the processor hardware reference manual for the encoding of this field.	access violation
liodn_handle	LIODN handle to the device that caused the error. This refers to the handle for the DMA-owning guest. If no valid LIODN handle exists this value is 0xffffffff.	access violation
eccctl	See the PAMU EECTL register in the hardware reference manual for definition.	single-bit ecc, multi-bit ecc
eccdis	See the PAMU EEDIS register in the hardware reference manual for definition.	single-bit ecc, multi-bit ecc
eccinten	See the PAMU EEINTEN register in the hardware reference manual for definition.	single-bit ecc multi-bit ecc
eccdet	See the PAMU EEDET register in the hardware reference manual for definition.	single-bit ecc multi-bit ecc
eccattr	See the PAMU EEATTR register in the hardware reference manual for definition.	single-bit ecc multi-bit ecc
eccaddr	The address that encountered an ECC error while reading from the cache	single-bit ecc multi-bit ecc
eccdata	See the PAMU EEDHI and EEDLO register in the hardware reference manual for definition.	single-bit ecc, multi-bit ecc
poes1	See the PAMU POES1 register in the hardware reference manual for definition.	operation
poeaddr	See the PAMU POEAH and POEAL register in the hardware reference manual for definition.	operation

11.1.2.6.8.7 CCF Error Domain

The CCF error domain represents error conditions related to the CoreNet Coherency Fabric.

Table 492. CCF Error Types

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Multiple intervention response	ccf	"multiple intervention"	Multiple interventions occurred for a given transaction.	disable, notify, halt, system-reset	disable
Local access error	ccf	"local access"	A transaction missed in a local access window.	disable, notify, halt, system-reset	disable

A structure within the general error structure (see Error Structure on page 2192) defines fields related to CCF error conditions.

The fields are shown below:

```
struct ccf_error {
        uint32_t cedr;
        uint32_t ceer;
        uint32_t cecar;
        uint64_t cecaddr;
        uint32_t cmecar;
} ccf_error_t;
```

The CCF error fields are defined as follows:

Table 493. CCF error fields

Fields	**Definition**	**Errors for Which the Field is Valid**
cedr	See the CCF CEDR register in the hardware reference manual for definition.	multiple intervention, local access
ceer	See the CCF CEER register in the hardware reference manual for definition.	multiple intervention, local access
cecar	See the CCF CECAR register in the hardware reference manual for definition.	multiple intervention, local access
cecaddr	See the CCF CECADRH and CECADRL registers in the hardware reference manual for definition.	multiple intervention, local access
cmecar	See the CCF CECAR2 register in the hardware reference manual for definition.	multiple intervention, local access

11.1.2.6.8.8 CPC Error Domain

The CPC error domain represents error conditions related to the CoreNet Platform Cache.

Table 494. CPC Error Types

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Tag multi-way hit	cpc	"tag multi-way hit"	A tag multi-way hit occurred.	disable, notify, halt, system-reset	disable
Tag or status multiple-bit ECC	cpc	"tag status multi-bit ecc"	A multi-bit ECC error occurred in a tag or status field.	disable, notify, halt, system-reset	disable
Tag or status single-bit ECC	cpc	"tag status single-bit ecc"	A single-bit ECC error occurred in a tag or status field. The *single-bit-ecc-threshold* property may be specified on the error configuration node for this error to set the policy of how many single bit ECC errors are to be tolerated before an error is asserted by the hardware. See Error Policy Configuration on page 2233. The default threshold is 8.	disable, notify, halt, system-reset	disable
Data multiple-bit ECC error	cpc	"data multi-bit ecc"	A multi-bit ECC error occurred in data.	disable, notify, halt, system-reset	disable
Data single-bit ECC error	cpc	"data single-bit ecc"	A single-bit ECC error occurred in data. The *single-bit-ecc-threshold* property may be specified on the error configuration node for this error to set the policy of how many single bit ECC errors are to be tolerated before an error is asserted by the hardware. See Error Policy Configuration on page 2233. The default threshold is 8.	disable, notify, halt, system-reset	notify

Table continues on the next page...

Table 494. CPC Error Types (continued)

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Configuration error	cpc	"config"	There was a platform cache configuration error.	disable, notify, halt, system-reset	disable

A structure within the general error structure (see Error Structure on page 2192) defines fields related to PAMU error conditions.

CPC error struct fields:

```
struct cpc_error {

        uint32_t cpcerrdet;

        uint64_t cpcerraddr;

        uint32_t cpcerrattr;

        uint32_t cpcerrctl;

        uint32_t cpcerrinten;

        uint32_t cpcerrdis;

        uint32_t cpccaptecc;

} cpc_error_t;
```

The common fields are defined as follows:

Table 495. CPC error fields

Fields	Definition	Errors for Which the Field is Valid
cpcerrdet	See the CPC CPCERRDET register in the hardware reference manual for definition.	all CPC error types
cpcerraddr	See the CPC CPCERRADDR and CPCERREADDR registers in the hardware reference manual for definition.	all CPC error types
cpcerrattr	See the CPC CPCERRATTR register in the hardware reference manual for definition.	all CPC error types

Table continues on the next page...

Table 495. CPC error fields (continued)

Fields	Definition	Errors for Which the Field is Valid
cpcerrctl	See the CPC CPCERRCTL register in the hardware reference manual for definition.	all CPC error types
cpcerrinten	See the CPC CPCERRINTEN register in the hardware reference manual for definition.	all CPC error types
cpcerrdis	See the CPC CPCERRDIS register in the hardware reference manual for definition.	all CPC error types
cpccaptecc	See the CCF CPCCAPTECC register in the hardware reference manual for definition.	all CPC error types

11.1.2.6.8.9 DDR Error Domain

The DDR error domain represents error conditions related to the DDR memory controllers.

Table 496. DDR Error Types

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Memory select error	ddr	"memory select"	A transaction request was issued to the DDR memory controller and the address does not lie within any of the programmed address ranges for an enabled chip select.	disable, notify, halt, system-reset	disable
Single bit ECC error	ddr	"single-bit ecc"	A single bit ECC error occurred and exceeded the configured threshold. The *single-bit-ecc-threshold* property may be specified on the error configuration node for this error to set the policy of how many single bit ECC errors are to be tolerated before an error is asserted by the hardware. See Error Policy Configuration on page 2233. The default threshold is 8.	disable, notify, halt, system-reset	disable
Multiple-bit ECC error	ddr	"multi-bit ecc"	A multi bit ECC error occurred at the memory controller.	disable, notify, halt, system-reset	disable

Table continues on the next page...

Table 496. DDR Error Types (continued)

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Corrupted data error	ddr	"corrupted data"	A data corruption error was detected.	disable, notify, halt, system-reset	disable
Automatic calibration error	ddr	"auto calibration"	This error is set if the memory controller detects an error during its training sequence.	disable, notify, halt, system-reset	disable
Address parity error	ddr	"address parity"	An address parity error was detected.	disable, notify, halt, system-reset	disable

A structure within the general error structure (see Error Structure on page 2192) defines fields related to DDR error conditions.

DDR error struct fields:

```
struct ddr_error {
        uint32_t ddrerrdet;
        uint32_t ddrerrdis;
        uint32_t ddrerrinten;
        uint32_t ddrerrattr;
        uint64_t ddrerraddr;
        uint32_t ddrsbeccmgmt;
        uint32_t ddrcaptecc;
} ddr_error_t;
```

The common fields are defined as follows:

Table 497. DDR error fields

Fields	Definition	Errors for Which the Field is Valid
ddrerrdet	See the DDR controller ERR_DETECT register in the hardware reference manual for definition.	all DDR error types
ddrerrdis	See the DDR controller ERR_DISABLE register in the hardware reference manual for definition.	all DDR error types
ddrerrinten	See the DDR controller ERR_INT_EN register in the hardware reference manual for definition.	all DDR error types
ddrerrattr	See the DDR controller CAPTURE_ATTRIBUTES register in the hardware reference manual for definition.	all DDR error types
ddrerraddr	See the DDR controller CAPTURE_ADDRESS and CAPTURE_EXT_ADDRESS registers in the hardware reference manual for definition.	all DDR error types
ddrsbeccmgmt	See the DDR controller ERR_SBE register in the hardware reference manual for definition.	all DDR error types
ddrcaptecc	See the DDR controller CAPTURE_ECC register in the hardware reference manual for definition.	all DDR error types

11.1.2.6.8.10 Miscellaneous Error Domain

The "misc" error domain represents miscellaneous error conditions that don't fit into the other domain types.

Table 498. Miscellaneous Error Types

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Internal RAM multi-bit ECC	misc	"internal ram multi-bit ecc"	An unspecified block in the SOC had a multi-bit ECC error. This error is catastrophic. The *system-reset* policy for this error utilizes a hardware mechanism that will reset the SOC directly with no hypervisor software intervention required.	disable, notify, halt, system-reset	disable

11.1.2.6.8.11 Machine Checks

Error conditions detected in a CPU may result in a machine check exception. See the CPU reference manual for a complete description of the hardware implementation of the interrupt model and machine check conditions in the CPU.

Guest Machine Checks

All machine check exceptions that occur while a CPU is executing in guest state are reflected to the guest partition to be handled by the guest's machine check handler, except for ICPERR and DCPERR which are recoverable and handled by the hypervisor and not reflected.

Guest machine checks are logged to the global event queue with the "machine check" error domain.

Hypervisor Machine Checks

Any machine check exception that occurs in the hypervisor (while the CPU is executing in hypervisor state, MSR[GS]=0) is non-recoverable, except for the following:

- ICPERR - Instruction cache tag or data array parity error. Recovery is automatically handled by the CPU hardware.
- DCPERR - Data cache data or tag parity error due to a load. If the L1 cache is in write-shadow mode the error is recoverable by the hypervisor. If the L1 cache is not in write-shadow mode the error is non-recoverable
- IF - Instruction fetch error report. IF is treated as non-fatal if accompanied by ICPERR.

Non-recoverable errors result in the hypervisor dumping register state to the console and halting all CPUs with interrupts disabled. If the hypervisor watchdog is enabled (see section Hypervisor Watchdog on page 2203) the system hardware will be reset.

Recoverable machine checks that occur in hypervisor state are logged to the global event queue with the "machine check" error domain.

Table 499. Machine checks

Error condition	Error Domain	Error Type String	Description	Allowable Policies	Default Policy
Machine check	machinecheck	"machine check"	A recoverable machine check condition was detected, or a machine check occurred in a guest partition.	notify	notify

A structure within the general error structure (see Error Structure on page 2192) defines fields related to DDR error conditions.

```
struct mcheck_error {

        uint32_t mcsr;

        uint64_t mcar;

        uint64_t mcsrr0;

        uint32_t mcsrr1;

} mcheck_error_t;
```

Table 500. Machine check error fields

Fields	Definition
mcsr	Value of the machine check syndrome register when the error occurred. See the CPU reference manual for specific field definitions.

Table continues on the next page...

Table 500. Machine check error fields (continued)

mcar	Value of the machine check address register when the error occurred. See the CPU reference manual for specific field definitions.
mcsrr0	Effective address of the instruction executing or about to execute when the error occurred. See the CPU reference manual for additional details.
mcsrr1	Value of the machine state register (MSR) when the error occurred.

11.1.2.6.8.12 Hypervisor Watchdog

The hypervisor implements a watchdog timer to detect severe system failures that require a system reset. If the watchdog is configured, the CPU's watchdog timer is enabled on all CPUs and the watchdog interrupt will fire periodically. The TSR[WIS] will be reset from within the watchdog interrupt handler. If the watchdog interrupt handler fails to run, the watchdog will expire and a system hardware reset will occur.

This approach enables recovery from unexpected exception conditions encountered in the hypervisor that result in a crash. Examples include:

- Memory corruption
- Severe hardware errors that prevent the normal exception handlers from running

See the *watchdog-enable* property defined in Hypervisor configuration node on page 2231.

The hypervisor watchdog timer handler also executes a customizable system health monitor routine that can periodically monitor system specific conditions to determine whether the system is in a healthy state. See System Health Monitor on page 2260 for details on how to customze the system health monitor.

11.1.2.6.9 Power management

11.1.2.6.9.1 Power Management Overview

The hypervisor provides mechanisms that allow partitions to access the power saving features in the processor hardware for controlling CPU power states.

A virtual CPU can be in one of several sleep states:

- RUN—the processor is running normally
- IDLE—instruction execution is suspended. CPUs request to enter this state with the FH_IDLE hcall and subsequent instructions initiate until an asynchronous interrupt occurs. The CPU is left in a standby mode in which cache snooping and time base interrupts are still enabled.
- NAP—all clocks to the functional units of the CPU are shut down, except the timebase. No cache snooping is performed in nap mode. CPUs enter this state with the FH_ENTER_NAP hcall. In NAP state decrementer, FIT, watchdog, and external interrupts are masked at the CPU by the hypervisor until the CPU is woken. Return to "run" state occurs when another CPU wakes up the napping CPU with the FH_EXIT_NAP hcall. NAP state is intended to be used for temporarily disabling **secondary** CPUs.

The FH_GET_CORE_STATE hcall allows a partition or a manager partition to read the sleep state of a CPU.

11.1.2.6.9.2 FH_GET_CORE_STATE

Hypercall: FH_GET_CORE_STATE

Description: Gets the sleep state for the virtual CPUs in a partition. Possible states are "run", "idle", and "nap".

Arguments:

Table 501. FH_GET_CORE_STATE Arguments

r11	hcall-token	FH_GET_CORE_STATE
r3	handle	Handle to the partition (-1 indicates current partition).
r4	vcpu	Number of the virtual cpu within the partition

Return values:

Table 502. FH_GET_CORE_STATE return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_ENOENT : the queue was empty EV_EINVAL: invalid parameter
r4	state	sleep state of the virtual CPU 0 : run 1 : idle 2 : nap

C API:

Table 503. FH_GET_CORE_STATE C API

unsigned int **fh_get_core_state**(unsigned int handle, unsigned int vcpu, unsigned int *state)

11.1.2.6.9.3 FH_ENTER_NAP

Hypercall: FH_ENTER_NAP

Description: A request put the specified virtual CPU to into NAP mode. Note, some implementations may only support the caller's virtual CPU as an argument and return EINVAL if other CPU numbers are specified.

Arguments:

Table 504. FH_ENTER_NAP Arguments

r11	hcall-token	FH_ENTER_NAP
r3	handle	Handle to the partition (-1 indicates current partition).
r4	vcpu	Number of the virtual cpu within the partition

Return values:

Table 505. FH_ENTER_NAP return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL: invalid parameter

C API:

Table 506. FH_ENTER_NAP C API

unsigned int **fh_enter_nap**(unsigned int handle, unsigned int vcpu)

11.1.2.6.9.4 FH_EXIT_NAP

Hypercall: FH_EXIT_NAP

Description: A request to remove the specified virtual CPU from NAP mode.

Arguments:

Table 507. FH_EXIT_NAP Arguments

r11	hcall-token	FH_EXIT_NAP
r3	handle	Handle to the partition (-1 indicates current partition).
r4	vcpu	Number of the virtual cpu within the partition

Return values:

Table 508. FH_EXIT_NAP return values

r3	status	Status of the hypercall 0 : the operation completed successfully EV_EINVAL: invalid parameter

C API:

Table 509. FH_EXIT_NAP C API

unsigned int **fh_exit_nap**(unsigned int handle, unsigned int vcpu)

11.1.2.6.10 High availability services

11.1.2.6.10.1 High Availability Service Overview

The hypervisor provides mechanism to create configurations where partitions can be arranged in an active and standby relationship. These mechanisms include:

- Notifications on managed partition state changes and watchdog expiration (see Partition Management Interrupts on page 2175)

- Device sharing between active and standby partitions. After an active partition crash, mechanisms exist for the new active partition to claim active ownership of shared devices, include interrupt routing re-configuration and IOMMU updates
- Error manager sharing between active and standby
- System reset if all partitions move into the stopped state (see sysreset-on-partition-stop property in Hypervisor Configuration Overview on page 2209).

11.1.2.6.10.2 Device Claiming

Devices can be shared between partitions in a failover configuration, whereby one partition has active ownership of a device at a time. Interrupts are routed to the active owner. Errors such PAMU access violations are placed in the error event queue of the active owner of the device.

If the active partition is stopped, another partition configured with access to the device may claim it and become the new active owner. To use this feature, all partitions assigned the shared device must specify the *claimable* property on the device configuration node for the device (see Device nodes on page 2222). At least one partition must have a shared device initially set to be "active".

When the "new active" partition claims a device, the interrupt configuration (priority, destination cpu) for that device will be reset to the default state. It is the responsibility of the new active partition to modify the interrupt configuration if necessary.

Claiming a device may also involve some reconfiguration of the PAMU and require DMA to be enabled for the claimed device. See DMA and Shared Devices on page 2224 for details.

11.1.2.6.10.2.1 Guest Device Tree Properties

A device node in the guest device tree contains several hypervisor specific properties that enable device drivers to determine status of a shared device and to claim a shared device on a failover.

Table 510. Guest Device Tree Shared Device Properties

Property Name	Usage	Value Type	Definition
fsl,hv-device-handle	SD	<u32>	May be present in a device node and provides a handle to perform device operations. Can be used in an fh_claim_device hcall.
fsl,hv-claimable	SD	<string>	Will be present in nodes identified as claimable in the hypervisor config tree. There are two possible values: "active"—The device is active—device interrupts and DMA errors are routed to the partition. "standby"—The device is 'standby' to this partition and should not be accessed. Interrupts and DMA errors will not be directed to a standby partition.

Table continues on the next page...

Table 510. Guest Device Tree Shared Device Properties (continued)

Property Name	Usage	Value Type	Definition
status	SD	<string>	Specifies the initial status of a device and will be present in a device node that is standby. It may be present in any other node. If the device is specified as "active" in the hypervisor configuration tree, any existing "status" property value set by boot firmware will be left as is, including possibly no status at all. If the device is specified as "standby" in the hypervisor config tree, the "status" property value will set to "disabled" if the existing status (in the hardware device tree) is "okay" or absent. If there is a non-ePAPR-compliant status that doesn't begin with "ok" it will be left alone.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.6.10.2.2 FH_CLAIM_DEVICE

Hypercall: FH_CLAIM_DEVICE

Description: The fh_claim_device hcall may be used to claim active ownership of a shared device or active ownership of error management.

For devices, invoking this hcall will result in the following changes:

- Interrupts for the device will be routed to the partition claiming ownership
- The PAMU may be reconfigured with updated true physical addresses of DMA windows if necessary (see DMA and Shared Devices on page 2224)
- Device specific errors, such as PAMU access violations, will be sent to the guest event queue of the partition claiming ownership.

In order to claim ownership of an interrupt inside an interrupt-map, the node containing the map has to be claimed, not the device node that maps to it.

If the target device is not already owned/claimed, an error will be returned.

In order to claim a device the partition currently owning the device must be in a "stopped" state.

Arguments:

Table 511. FH_CLAIM_DEVIC Arguments

r11	hcall-token	FH_CLAIM_DEVICE

11.1.2.6.11 Warm boot

11.1.2.6.11.1 Warm Boot Overview

Some systems may have mechanisms that allow the system to be warm booted—i.e. the system is restarted from the bootloader, but no hardware reset of the system or CPUs is required. In a warm boot memory and I/O devices may not need to be reinitialized. It may be required that the system be kept alive across a warm boot which means that certain regions of memory must maintain their contents and any I/O devices doing DMA must continue to operate normally and must not be stopped. During the warm boot the hypervisor image would be reloaded and the hypervisor would be started from its entry point.

A system can potentially use a warm boot to upgrade the hypervisor itself, where the hypervisor image loaded during the warm boot process is a new, upgraded image.

11.1.2.6.11.2 Warm Boot Details

A custom, system-specific mechanism must be created to perform the warm boot of a system. This may involve a custom hypercall or a customization of the fh_system_reset() hypercall (see Custom Reset on page 2260).

Warm boot support is enabled/disabled in the hypervisor at compile time with the CONFIG_WARM_REBOOT kconfig option.

When the warm boot feature is used the following should be noted:

- The activation of warm boot mode is done by a hypervisor command line parameter "warm-reboot", passed using the hardware device tree *bootargs* property (see Bootargs on page 2210). If this parameter is present, after verification of the integrity of the hypervisor- persistent data, the hypervisor initialization process bypasses any initialization that would affect any in-flight DMA.
- The Peripheral Access Management Unit (PAMU) tables are maintained in a distinct "persistent data" area defined within the hypervisor private memory. This region must be defined by the system architect in the hypervisor configuration tree with the *hv-persistent-data* property. This persistent region contains additional information necessary to complete the warm-reboot phase. The hypervisor owns its content, which includes a version number, and it must not be modified. Refer to Hypervisor Private Memory on page 2232 for information on the *hv-persistent-data* property.
- The *zero-pma* property (see PMA Hypervisor Configuration Tree Representation on page 2211) which directs the hypervisor to set the content of a guest physical memory area to zero is ignored on a warm-reboot phase in order to preserve the memory's contents.

The following additional assumptions should be noted:

- It is assumed that the configuration tree passed to the hypervisor on the warm boot is identical to the configuration tree passed at cold boot. This means that all device and memory partitioning is identical and that the memory requirements of an upgraded hypervisor must fit within the memory allocated to the hypervisor in that configuration tree.

- It is assumed that the configuration tree passed will reflect the active/standby state of the system at the time it was warm booted—i.e the "claimable" property on the device node specifies the active owner.
- Any guest device tree updates made with the FH_PARTITION_SET_DTPROP hcall will be lost across a warm reboot.

11.1.2.7 Configuration

The hypervisor software is configurable via a combination of compile time and static configuration parameters passed at boot time. This chapter describes the configuration parameters passed to the hypervisor at boot time.

11.1.2.7.1 Hypervisor configuration

11.1.2.7.1.1 Hypervisor Configuration Overview

The hypervisor is passed a hardware device tree when it is booted that describes all the hardware in the system.

A separate binary blob of configuration information is passed by address to the hypervisor using the bootargs parameter on the hardware device tree's */chosen* node. The hypervisor configuration tree contains all hypervisor configuration parameters and partition definition information. Based on the information in the hypervisor configuration tree the hypervisor will dynamically create guest device trees for each partition.

The hypervisor configuration tree is physically a device tree, but is in a custom form for hypervisor use only and is not ePAPR compliant.

The hypervisor configuration tree specifies all configurable parameters and all partitions, including:

- Physical memory areas (PMAs)—specifies how physical memory is partitioned
- DMA windows—a set of tables that each define a guest physical map of regions to which DMA devices are allowed to access
- Byte-channel mux—the declaration of any byte-channel muxes
- Doorbells—a table that declares all doorbells
- General hypervisor configuration parameters
- Partition declaration—each partition has a partition node that specifies properties of the partition. For example:
  - Set of physical CPUs in the partition
  - List of guest physical memory areas (each referencing a physical memory area)
  - Device nodes—a set of nodes which assign I/O devices and portals to a partition. For DMA-capable devices the node describes which DMA window table the device should use
  - Image load table
  - Guest address where the device tree should be placed
  - Doorbells assigned to the partition
  - Byte-channels—a table that defines all byte-channels in the partition and the uart or mux endpoints each is attached to
  - Guest aliases
  - Guest chosen node
  - Managed partition relationships

11.1.2.7.1.2 Hypervisor configuration- General

11.1.2.7.1.2.1 Hypervisor Configuration Tree

The hypervisor configuration tree is represented as a device tree. However, it does not describe hardware and is not ePAPR compliant. It is specifically designed for hypervisor configuration.

All addresses in the hypervisor configuration tree are 64-bits and consist of two cells.

The root node of the hypervisor configuration tree must contain a compatible property that identifies the device tree as a hypervisor:

Table 514. Root Mode Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "fsl-hv-config"
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.1.2.2 Bootargs

When the hypervisor is booted by boot firmware it must be passed the address of the hypervisor configuration tree in the *bootargs* property of the /chosen node in the hardware device tree. Multiple parameters in the command line are separated by spaces.

The bootargs property must include the following value:

```
config-addr=[physical address of device tree]
```

The physical address may be expressed in decimal, hexadecimal (0xNNN), or binary (0bNNN).

An optional bootargs parameter is:

```
warm-reboot
```

This indicates that the hypervisor is being started following a warm system boot in warm boot mode. See Warm boot on page 2208 for details.

11.1.2.7.1.3 Physical memory areas (PMA)

11.1.2.7.1.3.1 PMA Overview

A key aspect of partitioning a system is to partition the system's physical memory. To do this physical memory is divided into physical memory areas (or PMAs). PMAs are statically defined by the system architect and cannot be changed dynamically in a running system. The hypervisor itself is also assigned a PMA for its internal use.

A PMA is defined with the following properties:

- True physical address (must be size aligned)
- Size (must be a power of 2)
- CPC partitioning—specifies one or more ways of the Corenet platform cache (CPC) to be allocated and dedicated to this PMA

Each PMA corresponds to a CoreNet coherence domain (CSDID). Coherence is implied—if a PMA is only referenced by one partition, the PMA is private to that partition and only CPUs within that partition are snooped to maintain cache coherency. For shared PMAs, all partitions that reference the PMA will have their CPUs listed in the CSDID for the PMA.

NOTE

The P4080 supports up to 32 CSDIDs. 3-4 will be reserved for hypervisor use and the remainder are available for use in partitioning—leaving about 28 PMAs allowed.

The hypervisor supports a mechanism to initialize a PMA to zeros during a cold boot of a system—see the *zero-pma* property.

11.1.2.7.1.3.2 PMA Hypervisor Configuration Tree Representation

Table 515. PMA Configuration tree Representation

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "phys-mem-area"
addr	R	<u64>	The true physical (real) address of the PMA
size	R	<u64>	The size of the PMA-must be a power of 2
allocate-cpc-ways	O	<prop-encoded-array>	An array of <u32> values each specifying a way of the CPC to allocate. Note: by default the Corenet platform cache (CPC) allocates all ways to all PMAs. If the *allocate-cpc-ways* property is specified for a PMA, the selected ways will be removed from the default pool of ways (used by all other PMAs) and only access to the PMAs that specifically reference the ways (using the *allocate-cpc-ways* property) will allocate from them.
zero-pma	O	<none>	If present causes the PMA to be initialized to zeros during the cold boot of a system. Note: if the hypervisor is being booted in warm-boot mode (see Warm boot on page 2208) this option is ignored.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.1.4 DMA windows

11.1.2.7.1.4.1 DMA Windows Overview

The IOMMU (PAMU) requires careful configuration to specify the allowable regions of guest physical address space that can be targeted by DMA-capable devices.

PAMU supports defining power-of-2 sized memory DMA windows which can be optionally subdivided into a power-of-2 number of subwindows. Please consult the chip Reference Manual for the maximum number of supported sub-windows. Subwindows enable the definition of regions that may be the target of DMA, but are discontiguous in guest physical space or true physical space.

In the context of the hypervisor, a DMA window is conceptually a table of guest physical memory regions that are the valid targets of a DMA operation. Each row of the table consist of a guest physical address and size

If a single address window is needed the DMA window is simply a table with one row defining the region.

If multiple, discontiguous (guest physical **or** true physical) address regions are needed, DMA sub-windows are used to represent and configure the regions. In this case, the DMA window is conceptually a table with a power-of-2 number of rows, with each row defining one sub-window. There are several key parameters in defining sub-windows that need to be understood:

- **Total size**. This is the total size of the overall DMA region being defined, encompassing all sub-windows. This must be a power of 2.
- **Base address**. This is the guest physical address at which the overall DMA region starts. This must be size aligned with the total size.

- **Sub-window count**. The number of sub-windows must be power-of-2. Please consult the chip Reference Manual for the maximum number of supported sub-windows.
- **Maximum sub-window size**. The maximum size of each subwindow is computed by: total-size / subwindow-count.
- **Sub-window starting address**. Each sub-window starts at an address computed by:
- overall-starting-address + (subwindow index * maximum-subwindow-size)
- **Sub-window size**. Each sub-window can specify a size that may be smaller than the maximum subwindow size.

An DMA window describes a particular configuration of guest address space and may be applicable to one or more partitions.

DMA windows are referenced by DMA-capable I/O devices in their device nodes. Each DMA-capable device expresses one or more logical I/O device numbers (LIODN) which uniquely identify the device. Each LIODN used must have a DMA window configured for it.

11.1.2.7.1.4.2 DMA Windows-Hypervisor Configuration Tree Representation

DMA windows are defined with the properties described in the following table:

Table 516. DMA Windows-Hypervisor Configuration Tree Representation

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "dma-window"
guest-addr	R	<u64>	The guest physical address of the base DMA window. Must be size-aligned with the size property
size	R	<u64>	The size of the base DMA window—must be a power of 2 between 4KiB and 64GiB.
subwindow-count	SD	<u32>	Must be present if subwindows are used. Value specifies the number of subwindows. Must be a power-of-2 number. Please consult the chip Reference Manual for the maximum number of supported subwindows.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

The dma-window node may optionally have child nodes describing subwindows. Subwindows are defined as child nodes of the dma-window node. Subwindow nodes are defined with the following properties:

Table 517. DMA Sub-windows-Hypervisor configuration tree Representation

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "dma-subwindow"
guest-addr	R	<u64>	The guest physical address of the subwindow. This address must fall within the base DMA window (see 6-3) and be aligned to the base DMA window size divided by the subwindow-count (see size and subwindow-count property in 6-3)
size	R	<u64>	The size of the subwindow—must be a power of 2 between 4KiB and 64GiB.

Table continues on the next page...

Table 517. DMA Sub-windows-Hypervisor configuration tree Representation (continued)

pcie-msi-subwindow	SD	<none>	The property value is a boolean and its presence specifies that the subwindow is to be used for PCI-E MSIs. The address of the MPIC MSIIRx register in this subwindow will be conveyed to the guest in the guest device tree.
srio-ccsr-subwindow	SD	<none>	The property value is a boolean and its presence specifies that the subwindow is to be used for RapidIO accesses into CCSR space. The RapidIO maintenance transactions are translated into memory accesses to the CCSR space and they must be authorized by PAMU. The sub-window with this property must cover the CCSR address region for the RapidIO interface.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

It is not required that all subwindows be defined. Only the sub-windows that define valid address ranges must be defined. This allows the definition of noncontiguous regions of guest physical address space that are the valid targets of DMA operations.

11.1.2.7.1.5 Global Doorbell Definition

A set of global doorbell configuration nodes are used to declare doorbells.

Each global doorbell node in the hypervisor configuration tree has the properties described below. Up to four "fast doorbells" may be defined (see Fast Doorbells on page 2175). Fast doorbells have lower latency than regular doorbells. A fast doorbell is declared by adding the string "fast-doorbell" on the global doorbell node.

Table 518. Doorbell Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "doorbell" To specify this doorbell as a fast doorbell, must include the string "fast-doorbell".
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.1.6 Byte-channel Mux Configuration

A byte-channel multiplexer is defined at the root of the hypervisor configuration tree. The properties are specified in the table below: This node is referenced by byte-channels that use a mux as an endpoint.

Table 519. Byte-channel Multiplexer Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "byte-channel-mux"
endpoint	R	<phandle>	A phandle to the device node representing the uart to which the byte-channel mux is connected.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.1.7 Guest device tree node updates

11.1.2.7.1.7.1 Guest Device Tree Node Updates Overview

When the hypervisor creates a new partition, it uses the hardware device tree and the hypervisor configuration tree as input to instantiate the partition and to create a guest device tree for the partition. A "node update" mechanism is provided that allows a system architect to control the hypervisor's generation of nodes in the guest device tree.

Updates are defined in special node with the name *node-update or node-update-phandle* which are placed in the hypervisor configuration tree.

11.1.2.7.1.7.2 node-update

The node-update node allows guest device tree nodes and properties to be added, deleted, and updated. This node has the special name *node-update* and it is placed on nodes in the configuration device tree.

By default the node-update node is **merged** with the guest device tree node it is targeting. This means that the properties and nodes under the *node-update* node are copied exactly as is to the guest device tree. In addition, several additional directives are supported:

- deleting properties
- deleting a child node (or an entire sub-tree)
- deleting all child nodes of the specified node
- updating string properties, by prepending a string value

The following nodes in the hypervisor configuration tree support node-update nodes:

- Device nodes (see Device nodes on page 2222)
- Doorbell nodes (see Inter-partition Doorbell Configuration on page 2228)
- Byte-channel nodes (see Byte-Channel Configuration on page 2228)
- Partition nodes (see Partition Node Properties on page 2215)
- Guest physical memory area nodes (see Guest Physical Memory Areas on page 2221)
- Global error manager node (see Error Manager on page 2229)

The node-update node supports updates to descendants of the node which the *node-update* modifies. Updates to descendants can be done by replicating the node hierarchy under the node-update node using the names of the descendant nodes.

Except for the property names in the table below, all properties under *node-update* will be copied exactly as is to the guest device tree. If the property already exists in the node it will be replaced. Note: phandle references will not be resolved for properties with phandle values. See the *node-update-phandle* node (node-update-phandle on page 2215) for node updates to properties with phandle values.

In addition to copying properties, the following special properties allow some additional control:

Table 520. Guest Device Tree Node Special Properties

Property Name	Usage	Value Type	Definition
delete-prop	O	<stringlist>	The value identifies one or more names of properties that should be deleted from the node.
delete-node	O	<stringlist>	The value identifies one or more names of nodes that should be deleted. The node and all descendants will be deleted.

Table continues on the next page...

Table 520. Guest Device Tree Node Special Properties (continued)

delete-subnodes	O	<none>	A Boolean property. Applicable to device nodes (see Section). If present specifies that only the node itself and no descendants are to be copied to the guest device tree.
prepend-stringlist	O	<stringlist>	The value is a string list that specifies one or more property name/value pairs. "prop-name1," "prop-value1," "prop-name2," "prop-value2," Each name/value pair consists of two strings-the first is the name of the property, the second is a string to prepend to the property. If the property does not already exist it will be created.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

NOTE

phandles values in node-update nodes are not supported. See node-update-phandle on page 2215, for information on updating properties with phandle values.

11.1.2.7.1.7.3 node-update-phandle

The only supported mechanism for updating properties with phandle values is a special node with the name *node-update-phandle.*

Each property listed under *node-update-phandle* has a property name with a value that specifies the hypervisor configuration tree phandle of the referenced node. Arrays of phandles are supported, but it is not supported to mix phandles and non-phandle values in the same property.

If one property references another node by phandle the node referenced **must** be assigned to the partition.

11.1.2.7.2 Partition definition

11.1.2.7.2.1 Partition Node Properties

Each partition is defined by a partition node.

A partitioned is defined by a set of properties on the main partition node (see table below) plus several subnodes. The properties specify various partition parameters. The subnodes specify:

- The guest physical memory areas that exist and how they map to physical memory areas (PMAs)
- The I/O devices that are assigned to a partition (direct I/O).
- Virtual devices such as byte-channels, doorbells, and partition management nodes
- Aliases to add to the guest device tree's /alias node
- Debug stub nodes that define the relationship between byte-channels and CPUs in a partition
- Modifications to be made to properties on the guest device tree's /chosen node
- Modifications to be made to properties on the guest device tree's root node

A partition node has the following properties:

Table 521. Partition Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "partition."
label	O	<string>	Specifies a text string that describes the partition. This string may be used by partition management tools to display a readable label for a partition. The value of the *label* property is automatically propagated to the root node of the guest device tree.
cpus	SD	<prop-encoded-array>	Array defining which physical CPUs belong to the partition. This value is a <prop-encoded-array> encoded as an arbitrary number of pairs *(cpu-index, count)*. *cpu-index* is a <u32> that specifies a cpu index of a cpu in the hardware device tree (the index is identical to the value of the "reg" property in cpu nodes) *count* is a <u32> that specifies the number of CPUs being enumerated. Each CPU identified in the cpus field is enumerated starting with zero from left to right. Example: cpus = <4 2> This identifies two CPUs starting at index 4—i.e. CPUs # 4 and 5. These physical CPUs have logical indexes of 0 and 1 within the partition. Note: On cores with multiple threads per core (e.g. e6500 dual-threaded core) the hardware threads are individually assigned to the partitions. The hypervisor will expose the vcpu to guests as a single-threaded core.
dtb-window	R	<prop-encoded-array>	Specifies a memory window where the guest device tree is to be loaded in guest memory. The value is a <prop-encoded-array> encoded as: < dtb-addr-start dtb-size> Where: • *dtb-addr* is a <u64> that specifies the guest physical address specifying the start of a memory range where the guest device tree is to be loaded. • *dtb-size* is a <u64> value specifying the size of the memory window for the DTB.

Table continues on the next page...

Table 521. Partition Node Properties (continued)

Property Name	Usage	Value Type	Definition
guest-image	SD	<prop-encoded-array>	Specifies an image to be loaded by the hypervisor prior to partition start. This is the image to which the hypervisor transfers control when starting the partition. The value is a triplet defined as follows: <*image-src-addr image-dest-addr size*> Where: • *image-src-addr* is a <u64> that specifies the source true physical address of an image to be loaded into the partition. The image may be a binary image or may be in ePAPR ELF format. • *image-dest-addr* is a <u64> that specifies the guest physical address within the partition's main memory segment. This must be a word aligned address. For ELF images this value can be -1, which specifies that load address is to be determined from the ELF image itself (see below). • *size* is a <u64> and specifies the size of the source address window the image is located in. This value must be nonzero and could be different than the actual source image size. For binary images this field does specify the size of the image. The following images types are supported: • ELF (Executable and Linking Format) • If the *image-dest-addr* equals -1, for files with an ELF header e_type field value of ET_EXEC, each PT_LOAD segment will be loaded at the physical address given by the program headers p_paddr field. • the entry point into the image is calculated from the offset between the v_addr field and the e_entry field in the ELF header. • uImage (u-boot Image format)—the entry point into the image is calculated from the offset between the load address and entry point. • Binary. For binary images, offset 0x0 in the image is treated as the entry point.

Table continues on the next page...

Table 521. Partition Node Properties (continued)

Property Name	Usage	Value Type	Definition
linux-rootfs	SD	<prop-encoded-array>	Specifies the address and size of a Linux root filesystem image to be loaded by the hypervisor prior to partition start. The value is a triplet defined as follows: <*image-src-addr image-dest-addr size*> Where: • *image-src-addr* is a <u64> that specifies the source true physical address of an image to be loaded into the partition. • *image-dest-addr* is a <u64> that specifies the guest physical address within the partition's main memory segment. This must be a word aligned address. • *size* is a <u64> specifies the size of the source address window the image is located in. This value must be nonzero and could be different than the actual source image size. For binary images this field does specify the size of the image. The following images types are supported: 1) uImage (u-boot Image format), 2) binary. In the guest device tree for this partition the *linux,initrd-start* and *linux,initrd-end* properties will be set in the /chosen node to reflect the guest physical start and end addresses of the rootfs image.

Table continues on the next page...

Table 521. Partition Node Properties (continued)

Property Name	Usage	Value Type	Definition
load-image-table	O	<prop-encoded-array>	Specifies the addresses of one or more supplementary images to be loaded by the hypervisor prior to partition start. The value is a prop-encoded array and is a table with one or more rows. Each row consists of a triplet defined as follows: <*image-src-addr image-dest-addr size*> Where: • *image-src-addr* is a <u64> that specifies the source true physical address of an image to be loaded into the partition. • *image-gphys-addr* is a <u64> that specifies the guest physical address within the partition's main memory segment. This must be a word aligned address. For ELF images this value can be -1, which specifies that load address is to be determined from the ELF image itself (see below). • *size* is a <u64> specifies the size of the source address window the image is located in. This value must be nonzero and could be different than the actual source image size. For binary images this field does specify the size of the image. The following images types are supported: 1) ELF (Executable and Linking Format), 2) uImage (u-boot Image format), 3) binary. • For ELF files, if the *image-dest-addr* equals -1 and the ELF header e_type field value is ET_EXEC, each PT_LOAD segment will be loaded at the physical address given by the program header's p_paddr field.
watchdog-timeout	O	<string>	If present this property overrides the default behavior of the TCR[WRC] bits that control whether a partition is reset on a CPU watchdog expiration. Allowable values are: "manager-notify"—Specifies that all manager partitions managing the current partition receive a "watchdog expiration" interrupt. "partition-stop"—Stop the partition with the expired watchdog. "partition-reset"—Restarts the partition with the expired watchdog.
watchdog-autostart-period	O	<u32>	If present, for each CPU belonging to the partition, hypervisor will automatically start the guest watchdog at guest boot, with a period taken from the value of this new property. Early during its boot process, the guest should overwrite the watchdog settings with its own settings before the watchdog expires. If it fails to do so, the watchdog will timeout and cause the hypervisor to execute the watchdog timeout action defined by the "watchdog-timeout" property. The format of the value is identical to the watchdog period set through the TCR register: it specifies one of 64-bit locations of the timebase used to signal a watchdog on a transition from 0 to 1.

Table continues on the next page...

Table 521. Partition Node Properties (continued)

Property Name	Usage	Value Type	Definition
guest-cache-lock-disable	O	<none>	If present defines that guest cache lock mode is disabled.
guest-debug-disable	O	<none>	If present defines that guest debug mode is disabled.
no-auto-start	O	<none>	If present specifies that this partition should not be started. All images specified should be loaded, but the partition should not be started.
mpic-direct-eoi	O	<none>	A Boolean property. If present, specifies that this partition is granted direct end-of-interrupt support. See Direct EOI on page 2174 for more information.
init-map-paddr	O	<u64>	Specifies the guest physical address at which the partition's boot IMA is to be located. This address must be size aligned with the *init-map-size* property. If not specified, the guest physical address of the boot IMA is 0x0. See Initial Mapped Areas on page 2156.
init-map-size	O	<u64>	Specifies the size of the partition's boot IMA in bytes. The size must be a power of 2 and must be a minimum of 4KiB bytes and a maximum of 4GiB. See Initial Mapped Areas on page 2156.
init-map-vaddr	O	<u64>	Specifies the effective address at which the boot IMA should be mapped. This address must be size aligned with the *init-map-size* property. If not specified, the effective address of the boot IMA is 0x0. See Initial Mapped Areas on page 2156.
privileged	O	<none>	A Boolean property that specifies if the partition is privileged. See Privileged Partitions on page 2158 for details on the capabilities of privileged partitions.

Table continues on the next page...

Table 521. Partition Node Properties (continued)

Property Name	Usage	Value Type	Definition
no-dma-disable	O	<none>	Specifying the boolean *no-dma-disable* property has the following effects for all DMA-capable devices assigned to the partition • DMA will automatically be enabled for all devices in the partition on a cold boot—i.e. it is never necessary to explicitly enable DMA for the device when a partition is booted. • DMA for the partition's devices can continue after a partition has been stopped. This option would typically be used in a scenario where an active and standby partition share a device that accesses shared memory. If the active partition crashes and is stopped, by default DMA would be stopped. The no-dma-disable property changes this behavior so DMA can continue. • The FH_PARTITION_DISABLE_DMA hcall will have no effect on any device in the partition
defer-dma-disable	O	<none>	DMA starts disabled on cold boot, and is disabled on a partition reset, but on a partition stop it is not disabled until the FH_PARTITION_DISABLE_DMA hcall requests it.
direct-guest-tlb-management	O	<none>	Allows direct guest TLB management. In this case tlbwe and tlbilx will be executed directly by the guest without hypervisor intervention. This feature is available only on e6500 cores.
direct-guest-tlb-miss	O	<none>	TLB miss interrupts will go directly to the guest.

11.1.2.7.2.2 Guest Physical Memory Areas

Each partition defines a set of guest physical memory areas (GPMAs) that map to PMAs (physical memory areas, see Physical memory areas (PMA) on page 2210). Each GPMA references an associated PMA and specifies the guest physical address to which the PMA should be mapped.

GPMAs are defined as child nodes of a partition node. A GPMA node supports the following properties:

Table 522. GPMA Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "guest-phys-mem-area."
phys-mem	R	<phandle>	Value is a phandle to the PMA (physical memory area) to which this GPMA is to be associated.

Table continues on the next page...

Table 522. GPMA Node Properties (continued)

Property Name	Usage	Value Type	Definition
guest-addr	O	<u64>	The guest physical address at which this GPMA should be mapped. If this property is not present the guest physical address will be identity mapped to the true physical (real) address of the region specified in the PMA. The guest-addr value must be aligned to the size of the associated PMA.
dma-only	O	<none>	If present, this property specifies that the memory region is not accessible by CPUs and is accessible by DMA devices only.

Node updates for GPMAs are supported.

A GPMA appears in the guest device tree as a standard memory node as defined by the ePAPR.

11.1.2.7.2.3 Device nodes

11.1.2.7.2.3.1 Device Nodes Overview

A "device" node is a child node of a partition node and is used to assign physical I/O devices to partitions. There are 2 types of devices represented by device nodes:

- standard devices—a device that does no DMA (e.g. UART)
- DMA devices—a device that is capable of doing DMA (e.g. DMA controller). Every device that performs DMA expresses a logical I/O device number (LIODN) that the platform IOMMU uses to authorize the access. Certain devices express multiple LIODNs and have some special characteristics in the hypervisor configuration tree.

Each type of device has some unique characteristics. Standard devices are the most straightforward and simply have a property that specifies the full path or alias to the node in the hardware device tree that represents the device being assigned to the partition.

The devices nodes appear in the guest device tree under a */devices* node.

DMA devices are represented with the device name (alias or full device tree path) and a reference to a DMA window (see DMA windows on page 2211) that identifies the guest physical address regions to which the device is allowed to DMA.

Qman Portals. Qman portals are unique in that they have multiple LIODNs associated with them that may be individually configured. Each LIODN is represented as a separate child node under the configuration node for the qman portal device and each has its own set of properties including the target DMA window for the logical device. See Device Nodes fsl,qman-portal on page 2225 for complete details.

Node updates for device nodes are supported.

11.1.2.7.2.3.2 Device Configuration Nodes

Device configuration nodes are represented with the following properties:

Table 523. Device Nodes

Property Name	Usage	Value Type	Definition
device	R	<string>	The alias or full path to the device.

Table continues on the next page...

Table 523. Device Nodes (continued)

Property Name	Usage	Value Type	Definition
map-ranges	O	<none>	If present defines that the parent bus address range specified in the *ranges* property should be addressable by guest software in the partition.
vcpu	SD	<u32>	The index of the virtual CPU within the assigned partition to which the device is associated. Currently applicable to nodes with a compatible value of "fsl,qman-portal" and "fsl,bman-portal" only.
claimable	O	<string>	The "claimable" property specifies that this device is being shared with another partition. A device configured like this can be claimed by a partition using the fh_claim_device hcall. Claiming a device causes the device to be active for the claiming partition and interrupts and DMA to be routed to the claiming partition. Allowable values include: "active"—The device is active—device interrupts and DMA errors are routed to the partition. "standby"—The device is 'standby' to this partition and should not be accessed. Interrupts and DMA errors will not be directed to a standby partition. Note: The "claimable" property specified on a device configuration node will apply to all descendant nodes of the assigned device—i.e. in the guest device tree all descendants of the node will be claimable.

In addition, the following properties specify the DMA-related characteristics of a device:

Table 524. Device Nodes, DMA-related properties

Property Name	Usage	Value Type	Definition
dma-window	SD	<phandle>	A phandle to the DMA window node in the hypervisor configuration tree that this device is allowed to target. This is required for DMA capable devices. A dma window specifies a set of guest physical address ranges that are the valid targets of DMA operations. For shared devices using the "claimable" mechanism, the dma-window property must be set on the "active" device only.
operation-mapping	SD	<u32>	Specifies an index in the PAMU operation mapping table. (See Qman portal assignment on page 2226 for a definition of valid values for this property)

Table continues on the next page...

Table 524. Device Nodes, DMA-related properties (continued)

Property Name	Usage	Value Type	Definition
stash-dest	SD	<u32>	Specifies which level in the hierarchy a stashing operation is to be directed. Valid values are as follows: 1: L1 cache 2: L2 cache 3: L3/CPC cache
snoop-cpu-only	SD	<none>	A Boolean property. If present specifies that the snoop traffic associated with the transaction should be restricted to only the core complex (cpu/cluster) the vcpu that this portal is associated with is part of.
liodn-index	SD	<prop-encoded-array>	Applicable to devices that have more than one LIODN. Specifies the index in the liodn property in the hardware device tree node with which this node is associated.
no-dma-disable	O	<none>	Specifying the boolean *no-dma-disable* property has the following effects: • DMA will automatically be enabled for the device on a cold boot—i.e. it is never necessary to explicitly enable DMA for the device when a partition is booted. • DMA for this device can continue after a partition has been stopped. This option would typically be used in a scenario where an active and standby partition share a device that accesses shared memory. If the active partition crashes and is stopped, by default DMA would be stopped. The no-dma-disable property changes this behavior so DMA can continue. • The FH_PARTITION_DISABLE_DMA hcall will have no effect on this device
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.2.3.3 DMA and Shared Devices

Devices can be shared between partitions in a failover configuration, whereby one partition has active ownership of a device at a time (see, High availability services on page 2205).

In this configuration the partitions that share the device each specify a claimable property indicating which partition is the initial active owner and which is standby.

The properties in Device Configuration Nodes on page 2222 that specify the DMA configuration of the device must be placed only in the device node that is the initial "active" device—i.e. standby devices must not specify a DMA configuration. When a shared device is claimed, the only reconfiguration of the PAMU that is performed by the hypervisor is an update of the true physical address of any DMA window that changed for the new active partition.

11.1.2.7.2.3.4 Propagation to Descendants

Certain properties of device nodes are applicable to descendants of the device in the hardware device tree to which the device node refers.

- **dma-window**. The *dma-window property* applies to all descendants of the device in the hardware device tree.

This behavior can be overridden for descendants of the base device by specifying a separate device node for the child node. See the Embedded Hypervisor User's Manual for an example.

11.1.2.7.2.3.5 simple-bus

For device nodes where all ancestors contain a compatible value of "simple-bus", and where no ancestor has been assigned to the partition, the hypervisor copies the node from the hardware device tree node to the root of the guest tree. Any *reg* and *ranges* properties which may have contained an offset, are updated to reflect the full physical address of the devices registers as mapped by any *ranges* properties in the ancestry of the node.

11.1.2.7.2.3.6 Device Nodes fsl,qman-portal

See Message Signaled Interrupts on page 2225 for a description of how Qman portals are assigned to a partition.

11.1.2.7.2.3.7 fsl,dpaa

For device nodes with a parent that contains a compatible value of "fsl,dpaa", both the node and parent are copied to the guest device tree.

11.1.2.7.2.3.8 fsl,p4080-pcie, fsl,p3041-pcie, fsl,p5020-pcie

11.1.2.7.2.3.8.1 Message Signaled Interrupts

PCI Express message signaled interrupts require special consideration.

1. Assignment of PCI and MSI nodes

   In the hardware device tree each PCI controller node references an associated MSI node which represents the MSI interrupt register bank in the MPIC. The fsl,msi property on the PCI controller node in the hardware device tree contains a phandle pointing to the MSI node. When assigning a PCI controller to a partition the corresponding MSI node must also be assigned.

   Each MSI bank supports 8 physical MPIC interrupts. Each of the 8 interrupts support 32 MSIs. When an MSI occurs, the guest software must read the interrupt handle via IACK or EPR and then invokes the **fh_vmpic_get_msir** hypercall to read the MSIRx (Shared message signaled interrupt register) which specifies which of the 32 interrupts occurred.

2. MSI Addresses

   PCI Express endpoints trigger message signaled interrupts by writing to the MPIC MSIIRx *(Shared message signaled interrupt index register)*. This 'MSI address' is programmed into the endpoints by the host PCI controller. There are two considerations related to the MSI address:

   PAMU configuration

   The endpoint access to write the MSI address is a normal memory write and thus must be authorized by PAMU. This requires that a special MSI subwindow be configured in the DMA setup for the PCI controller (see the *pcie-msi-subwindow* property) which specifies the guest physical address of the page where the MSIIRx register is located.

   The MSI address goes through a translation from PCI address space to a system address via the ATMUs in the PCI controller. Care must be taken to configure the inbound ATMU so the resulting system address hits in the MSI subwindow.

   msi-address-64

   The *msi-address-64* property will be set on the PCI controller node in the guest device tree and will contain the address in PCI address space to which endpoints should write to trigger MSIs.

3. MSI nodes

   MSI nodes contain the array of interrupt specifiers for each of the 8 MSI interrupts. See Interrupt Controller Services on page 2171 for additional detail on processing MSIs.

11.1.2.7.2.4 Qman portal assignment

Qman portals are represented in the hardware device tree with a node containing a compatible value of "fsl,qman-portal." Qman portals express six different LIODNs:

- Fman0
- Fman1
- SEC
- PME
- Dequeue data stashing
- Dequeue DQRR stashing

Qman portals are typically associated with physical CPUs, and thus a normal configuration would assign one Qman portal to a partition per physical CPU assigned.

There are 2 components involved in assigning Qman portal devices:

- Definition of a portal-devices node, that is common to all Qman portals in the partition
- A device assignment node for each Qman portal assigned to the partition

11.1.2.7.2.4.1 portal-devices

The Fman0, Fman1, SEC, and PME portal devices will share a common configuration for all portals assigned to a partition. This configuration is specified under a special portal-devices device configuration node.

The portal-devices node must be a child of the partition node and have the name "*portal-devices*".

Under the *portal-devices* node Fman0, Fman1, SEC, and PME must each define a subnode with the device configuration node as described in Device Configuration Nodes on page 2222:

- Fman0 and Fman1 must have a device property specifying the device tree path (or alias) to the respective hardware fman node and a *dma-window* property
- SEC subnodes must have a device property specifying the device tree path (or alias) to the hardware SEC node and a *dma-window* property specified
- PME subnodes must have a device property specifying the device tree path (or alias) to the hardware pme node and a *dma-window* property specified

See the NXP Embedded Hypervisor User's Manual for examples.

11.1.2.7.2.4.2 fsl,qman-portal

Qman portals are assigned to a partition like other hardware I/O devices using device configuration nodes as described in Device Configuration Nodes on page 2222. However, in addition under the partition configuration node Qman portals use two child nodes to represent the two stashing LIODNs expressed by the portal:

- Dequeue data stashing
- Dequeue DQRR stashing

The primary portal device configuration node may have the following 2 properties

- *device*—the value specifies the full path to the qman portal
- *vcpu*—the value specifies the virtual or logical cpu index with which the portal is to be associated. This property is optional and should be specified if a binding between portal and cpu is desired. If the vcpu property is present the *cpu-handle* property in the hardware device tree node will be updated with a phandle to the physical cpu node.

The subnodes use the properties described in Device Configuration Nodes on page 2222, but have the following additional requirements:

- Dequeue DQRR stashing subnode

- must have a *dma-window* property specified
- must have an *liodn-index* property with a value of 0
- must have an *operation-mapping* property set with the index of the Qman stashing operation mapping entry
- must have a *stash-dest* property which specifies the cache the stash is targeting
- can optionally have a snoop-cpu-only property specified

- Dequeue data stashing subnode
  - must have a *dma-window* property specified
  - must have an *liodn-index* property with a value of 1
  - must have an *operation-mapping* property set with the index of the Qman stashing operation mapping entry
  - must have a *stash-dest* property which specifies the cache the stash is targeting

See the NXP Embedded Hypervisor User's Manual for examples.

11.1.2.7.2.5 Operation Mapping Table Index

The table below defines the operation mapping table indexes that may be used as values in the *operation-mapping* property on device configuration nodes (see Device Configuration Nodes on page 2222).

Table 525. Operation Mapping Table Index Definition

Index	Device	Ingress Operation	Egress Operation
0	Qman	READ	READ
		EREAD0 (Enhanced read type 0)	RSA (Read with stash allocate)
		WRITE	WRITE
		EWRITE0 (Enhanced write type 0)	WWSAO (Write with stash allocate only)
		DIRECT0 (Directive type 0)	LDEC (Load external cache)
		DIRECT1 (Directive type 1)	LDECPE (Load external cache with preferred exclusive)
1	Fman	READ	READI (Read with invalidate)
		WRITE	WRITE
2	Qman Private	READ	READ
		WRITE	WRITE
		EREAD0 (Enhanced read type 0)	RSA (Read with stash allocate)
		EWRITE0 (Enhanced write type 0)	WWSA (Write with stash allocate)
3	SEC	READ	READI (Read with invalidate)
		WRITE	WRITE

11.1.2.7.2.6 Byte-Channel Configuration

Byte-channel endpoints are defined as nodes under the partition node. Each byte-channel node may have the following properties:

Table 526. Byte-Channel Node Properties (Hypervisor Configuration)

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "byte-channel."
endpoint	R	<phandle>	A phandle to the endpoint to which the byte channel is connected. Valid values are as follows: • A device node pointing to a physical UART • a byte-channel mux • another byte-channel node
mux-channel	SD	<u32>	Specifies the mux channel number. Required if the endpoint property points to a byte-channel mux
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

Node updates for byte-channel nodes are supported.

11.1.2.7.2.7 Inter-partition Doorbell Configuration

Doorbell send and receive endpoints are declared as nodes under the partition node. These nodes reference the global doorbell node with which they are associated.

Supported properties are shown in the table below:

Table 527. Doorbell Configuration Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	For receive doorbell endpoints must include "receive-doorbell." For send doorbell endpoints, must include "send-doorbell"
global-doorbell	R	<phandle>	Value is a phandle to the global doorbell node to which this endpoint is associated.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

Node updates for doorbell nodes are supported.

11.1.2.7.2.8 Partition Management Nodes

If the partition being defined via the partition node manages other partitions, this relationship is expressed by declaring a node that references the managed partition.

It is supported to have partitions that "manage" each other. This can be used to create high availability scenarios where partitions are notified about the state of a partition that they manage/monitor.

Supported properties are shown in the table below:

Table 528. Partition Management Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "managed-partition."
partition	R	<phandle>	Value is a phandle to the partition node which is to be managed by this partition. This property results in a partition management handle node to be placed under the manager partitions /hypervisor/handles node in its guest device tree. In addition, this property results in a set of partition management doorbells to be placed under the manager partition's /hypervisor/handles node in its guest device tree.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.2.9 Error Manager

A partition is designated to be an "error manager" by defining an error manager node as a child of the partition node. See Error Management on page 2188, for details on error management.

Table 529. Error Manager Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<stringlist>	Must include "error-manager". Specifies that this partition is an error manager.
vcpu	R	<u32>	Specifies the vcpu number within the partition that is to receive interrupts for global errors
claimable	O	<string>	The "claimable" property specifies that error management is being shared with another partition in a failover configuration. Error management responsibilities can be claimed by a partition using the fh_claim_device hcall. Valid values are: "active" - The partition is the active error manager "standby" - The partition is the standby error manager
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

Node updates for the error manager node is supported.

11.1.2.7.2.10 Guest Aliases

By default all assigned devices that have an alias in the hardware device tree will have that alias copied to the guest device tree.

In addition, a guest aliases node can be specified under a partition node to add additional aliases to the guest device tree. The name of this node must be aliases. The value must be a phandle to a node in the hypervisor configuration tree. The phandle values are resolved to a string value that is the full path to the referenced object in the guest device tree.

11.1.2.7.2.11 Guest Root Node Properties

The partition node supports *a node-update* node which updates the root node of the guest device tree.

11.1.2.7.2.12 Debug Stub Node

The hypervisor supports debug agents or stubs (built into the hypervisor) which may be use to debug guest software running in a partition. A byte-channel provides a communications channel from the stub to a host debugger.

To instantiate a debug stub for a partition a *debug-stub* node must be present as a child of the partition node (see Partition Node Properties on page 2215) which defines the properties of the stub.

Note: all debug stub nodes within a partition must be of the same type—i.e. the *compatible* string must be the same.

Debug stubs require the CPU's debug resources (debug registers and debug interrupt) for normal operation. This means that guest debug mode must be turned off, granting the debug resources to the hypervisor. See the *guest-debug-disable* property for partition nodes (section Partition Node Properties on page 2215).

Table 530. Debug Stub Node Properties

Property Name	Usage	Value Type	Definition
compatible	R	<string>	For GDB must include "gdb-stub," "debug-stub" For TRK must include "trk-stub", "debug-stub"
endpoint	R	<phandle>	Specifies the phandle of the byte-channel endpoint to which this stub is to be attached. Valid values are as follows: • A device node pointing to a physical UART • a byte-channel mux • another byte-channel node
mux-channel	SD	<u32>	Specifies the mux channel number. Required if the endpoint property points to a byte-channel mux
debug-cpus	O	<prop-encoded-array>	Array defining which virtual CPUs are to be debugged by the debug stub. This value is a <prop-encoded-array> encoded as an arbitrary number of pairs *(cpu-index, count)*. *cpu-index* is a <u32> that specifies a cpu index from the guest device tree (the index is identical to the value of the "reg" property in cpu nodes) *count* is a <u32> that specifies the number of CPUs being enumerated. If this property is not present the hypervisor will assume that all CPUs in the partition are to be debugged by this stub.
gdb-wait-at-start	O	<none>	Applicable to gdb stub nodes only (compatible = "gdb-stub"). If present specifies that the gdb stub should halt the guest OS prior to execution of the first instruction of the guest (its entry point) and wait for the host debugger to attach.

NOTE

There is an experimental hypervisor configuration option that enables debugging using the program interrupt instead using the CPU debug resources. This option may be used if there is a requirement to use a debug stub while enabling guest debug mode for a partition. See CONFIG_DEBUG_STUB_PROGRAM_INTERRUPT

11.1.2.7.3 Structure of Guest Device Trees

Partitions are passed an ePAPR compliant guest device tree. A guest device tree describes all the resources available to the partition. This includes nodes describing hardware devices, as well as nodes describing virtual devices.

Root node properties. Guest device trees will have a root node with the following standard ePAPR properties copied intact from the hardware device tree

- *epapr-version*
- *#address-cells*
- *#size-cells*

In addition, the *compatible* property on the root node will have the string "simple-bus" added to the stringlist if it is not already present.

The root node can be updated with a *node-update* property.

I/O Devices. Devices assigned to a partition by a device node will be placed at the root of the guest device tree.

Hypervisor node. Each guest will have a hypervisor node at the root of the guest device tree. The hypervisor node contains properties and handles to be used by a guest.

11.1.2.7.4 Hypervisor configuration node

The hypervisor is also configured via the hypervisor configuration tree. A special node and subtree defines set of global configuration parameters and a number of device nodes assigning I/O devices to the hypervisor:

Configuration parameters specify the hypervisor's console, the hypervisor's private memory, and interrupt configuration. The parameters are described in the following table.

Table 531. Hypervisor configuration parameters

Property Name	Usage	Value Type	Definition
compatible	R	<string>	Must include "hv-config."
stdout	O	<phandle>	phandle to a serial device or byte-channel which should be used for the hypervisor's console. This property takes precedence over any *stdout* alias set in the hardware device tree.
sysreset-on-partition-stop	O	<none>	If present this property specifies that if all partitions move into the "stopped" state that the system should be reset.

Table continues on the next page...

Table 531. Hypervisor configuration parameters (continued)

Property Name	Usage	Value Type	Definition
watchdog-enable	O	<u32>	If present defines specifies that the hypervisor watchdog is to be enabled (on all CPUs). The value specifies the watchdog timer period. The value specifies one of 64-bit locations of the time base used to signal a watchdog timer exception on a transition from 0 to 1. 0 - selects TBU[32], the msb of the timebase 63 - selects TBL[63], the lsb of the timebase
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.4.1 Hypervisor Private Memory

The hypervisor requires a region of physical memory for its private use. A child node of the hypervisor configuration node defines this region (similar to a guest physical memory area):

Table 532. Hypervisor Subnode Properties

Property Name	Usage	Value Type	Definition
compatible	R	<string>	Must include "hv-memory."
phys-mem	R	<phandle>	Value is a phandle to the PMA (physical memory area) which is assigned to the hypervisor..
hv-persistent-data	O	<prop-encoded-array>	If present, it defines a memory region within the hypervisor's memory where PAMU-related data structures are located. The value specifies the offset and size within the memory area. The region include a 4KiB region at the beginning reserved for hypervisor use (for PAMU-related hypervisor housekeeping). The property value is a prop-encoded-array consisting of 4 cells defined as: <offset-hi offset-lo size-hi size-lo> offset-hi | offset-lo - a pair of <u32> specifying the offset in the memory area where the hypervisor persistent data begins size-hi | size-lo - a pair of <u32> cells specifying the size of the memory area The size of the memory region is SoC dependent. Contact NXP support for recommendation for the value of the size.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.4.2 Hypervisor Owned I/O Devices

A number of SOC devices must be assigned to the hypervisor. These are assigned using device assignment nodes which are children of the *hypervisor configuration node*. The device assignment nodes definition use a syntax identical to that of assigning devices to partitions (see Device nodes on page 2222).

For hypervisor owned serial ports the baud rate is configured as follows—if the serial port device node in the hardware device tree passed to the hypervisor has a *current-speed* property, that speed will be used. Otherwise, if the device assignment node for the serial device has a *baud* property (see table below) the value of that property is used. If neither property is present a baud rate of 115200 is used.

Table 533. *baud* property

Property Name	Usage	Value Type	Definition
baud	O	<u32>	Specifies the baud rate to be used for the hypervisor console when it is attached to a serial port (see Hypervisor Console Configuration on page 2234). This property is valid on a device assignment node for a serial device that is a child of the hypervisor configuration node. This property takes precedence over any current-speed property set in the hardware device tree.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

For all serial configurations the following serial port parameters are assumed:

- data bits: 8
- parity: none
- stop bits: 1

NOTE

For the QorIQ SoCs the following devices must be assigned to the hypervisor for proper operation:

- Interrupt controller (compatible "chrp,open-pic")
- Corenet local access windows (compatible "fsl,corenet-law")
- Corenet coherency fabric (compatible "fsl,corenet-cf")
- Memory controllers (e.g. compatible ""fsl,p4080-memory-controller")
- Platform cache controllers (e.g. compatible "fsl,p4080-l3-cache-controller")
- IOMMU (e.g. compatible "fsl,p4080-pamu")
- Global utilities (e.g. compatible "fsl,qoriq-device-config-1.0")

11.1.2.7.4.3 Error Policy Configuration

For hypervisor owned devices (see Hypervisor Owned I/O Devices on page 2232), an error handling policy may be configured, which would override the default policy for the error. Default policies are defined in , . An error configuration node is used to define error policies.

Table 534. Error Policy Properties

Property Name	Usage	Value Type	Definition
compatible	R	<string>	Must include "error-config."
Table continues on the next page...			

Table 534. Error Policy Properties (continued)

Property Name	Usage	Value Type	Definition
domain	R	<string>	Specifies the domain of the error. See Error Domains, Error Types, Error Policies on page 2190 for a list of error domain strings.
error	R	<string>	Specifies the error type the policy applies to. See Error Domains, Error Types, Error Policies on page 2190 for a list of error type strings.
policy	R	<string>	Specifies the policy for the error. Valid policies are: "disable" - error is ignored/masked "notify" - notification to global event queue "halt" - hypervisor halts "system-reset" - hardware system reset
single-bit-ecc-threshold	O	<u32>	A value from 0 to 256 that specifies how many single bit ECC errors are to be tolerated before an error is asserted by the hardware.
Usage legend: R=Required, O=Optional, OR=Optional but Recommended, SD=See Definition			

11.1.2.7.4.4 Hypervisor Owned Byte-channels

A byte-channel can be defined to be the hypervisor's console. A node defining a hypervisor-owned byte-channel is a child of the hypervisor configuration node and the definition is identical to that of byte-channels under partition nodes (see Byte-Channel Configuration on page 2228).

11.1.2.7.4.5 Hypervisor Console Configuration

The hypervisor provides support for a console that can be used for debugging. It provides informational and error messages and an interactive shell that can be used to display hypervisor status and state.

The console can be attached to either a UART or byte-channel.

If the *stdout* alias is specified in the hardware device tree, the serial device referenced will be used as the console, unless overridden by the *stdout* property on the hypervisor configuration node specifies the console device (see Hypervisor configuration node on page 2231).

The console device must be A) assigned to the hypervisor (UART), or B) defined (byte-channel) in the hypervisor configuration node.

11.1.2.8 Debugging

11.1.2.8.1 Hypervisor Console and Shell

The hypervisor has a console which is may be attached to a uart or byte-channel. The console is used by the hypervisor to print error and warning messages. In addition, through a compile time configuration option, a debug command prompt can be enabled that supports some commands that provide greater visibility into the partition and hypervisor state.

The console to byte-channel connection definition is specified in the stdout property in the hypervisor configuration node (see Hypervisor configuration node on page 2231).

Table 535. Supported Shell Commands

Command	Description
buildconfig	Display build time configuration options
cdt	Display hypervisor configuration tree
error_policy	Display error policies
gdt print <partition#>	Displays the guest device tree. Partition number can be displayed by the **info** command.
gtlb <partition #> <vcpu#>	Displays the guest TLB for the specified partition and virtual CPU.
guestmem <partition-#> <address> [<length>]	Displays guest memory by guest physical address
help [command]	If the *command* argument is not specified, lists all the shell commands with a short help message.
hdt	Displays the hardware device tree.
info	Lists the partitions that exist and their current status. The partition numbers displayed with this command are used in other shell commands.
paact	Displays the PAACT table for the PAMU.
pause	Pauses a running partition. In this state the partition halts execution and all interrupts are disabled.
reset	Resets the system-asserts the reset request signal.
restart <partition #>	Restarts a running partition. This includes loading hypervisor-loaded images. NOTE: **restart** honors the optional no-auto-start property that can be present on partition nodes. If no-auto-start is present, images are loaded but the partition is not started.
resume	Resumes a paused partition.
start [load] <partition #>	Starts a stopped partition. If the load argument is specified any hypervisor loaded images specified in the hypervisor configuration tree are loaded as well. NOTE: **start load** <partition #> honors the optional no-auto-start property that can be present on partition nodes. The effect of **start load** with no-auto-start is that images are loaded but the partition is not started.
stop	Stops a running partition.
version	Displays the version of the hypervisor.

Table continues on the next page...

Table 535. Supported Shell Commands (continued)

Command	Description
loglevel [group] [level]	Changes the current log-level of the specified logging group. Use the command with no arguments to display the groups and their current log levels. Log level 0 disables logging and log level 15 is the most verbose. Setting higher levels may be dangerous (e.g enabling debug on a byte-channel mux (bcmux) when the hypervisor console is on the mux).

NOTE

The shell command syntax is preliminary and subject to change in future releases of the hypervisor.

11.1.2.8.2 GDB Debug Stub

11.1.2.8.2.1 GDB Debug Stub Overview

The hypervisor can act as a remote target for the GNU Debugger (GDB). This provides the capability to debug guest software running in a partition.

The hypervisor implements support for the *gdb Remote Serial Protocol* as described in version 6.7 of the gnu Debugger (GDB) reference manual. (See Appendix D of *Debugging with gdb, The gnu Source-Level Debugger*.

The hypervisor also supports the target description format as defined in *Target Descriptions*, Appendix F of the GDB 6.7 reference manual.

The gdb stub supports limited debugging capabilities for SMP guests. One stub per CPU must be defined and a separate GDB host debugger per stub must be used. Hardware breakpoints must be used for setting breakpoints for SMP guests. See Debug Stub Node on page 2230, for details on configuring stubs in the hypervisor configuration tree.

11.1.2.8.2.2 Supported GDB Commands

The hypervisor gdb stub supports the following commands designated as required by the GDB manual:

- 'g' (Read register)
- 'D' (detach)
- 'G' (write register)
- 'm' (read memory)
- 'M' (write memory)
- 'c' (continue)
- 's' (Single step)

The hypervisor gdb stub also support the following commands:

- '?' (indicates reason target halted)
- z0 and Z0 (set/remove memory breakpoints)
- z1 and Z1 (set/remove hardware breakpoints)

The stub supports two hardware breakpoints.

- z2 and Z2 (set/remove write watchpoint)
- z4 and Z4 (set/remove access watchpoint)

The general query packet 'qXfer:features:read' which provides access to the target description XML file

- p (read_register)
- P (write_register)
- qOffsets (get section offsets)
- qSupported (supported_features)
- D (detach)
- X (raw_write)
- qRcmd (monitor)

supports a "restart" command to restart a partition

- k (kill)

11.1.2.9 Byte-Channel Serial Multiplexer Protocol

11.1.2.9.1 Byte-Channel Serial Multiplexer Protocol Overview

The hypervisor implements a byte-channel multiplexer which can multiplex up to 32 byte-channels over a serial RS232 link.

The multiplexer implements an escape-sequence based channel switching protocol. An escape sequence sets the 'current channel' and all data that follows belongs to that channel until a new current channel is set which changes the channel.

The byte value 0x18 (CTRL-X character) specifies the start of an escape sequence. The byte following the 'escape sequence start' is an escape sequence **command**.

Up to 32 channels are supported.

11.1.2.9.2 Escape Sequence Commands

Table 536. Escape Sequence Commands

Escape Sequence and Command	Meaning
0x18 0x00	Reserved
0x18 0x01	TX reset -- tells the remote end to retransmit the tx channel switch the next time it transmits even if on the same channel as before
0x18 0x02-0x18 0x2F	Reserved
0x18 0x30	Set current channel to 0
0x18 0x31	Set current channel to 1
0x18 0x32	Set current channel to 2
0x18 0x33	Set current channel to 3
0x18 0x34-0x18 0x4F	Set current channel to 4-31
0x18 0x50-0x18 0x7F	Reserved
0x18 0x18	Send the character 0x18 through as data

11.1.2.10 Linux hypervisor management driver

11.1.2.10.1 Linux Hypervisor Management Driver Overview

A Linux character device driver allows user space access to certain hypervisor services for partition management. This section documents the ioctl API provided by this device driver.

All the IOCTLs are defined in the Linux header file: fsl_hypervisor.h

11.1.2.10.2 FSL_HV_IOCTL_PARTITION_RESTART

IOCTL code: FSL_HV_IOCTL_PARTITION_RESTART

Description: Restart a running partition

FSL_HV_IOCTL_PARTITION_RESTART takes a **fsl_hv_ioctl_restart** structure as an argument.

Table 537. FSL_HV_IOCTL_PARTITION_RESTART fields

Parameter	Description
__u32 partition	An input parameter. Partition ID to restart, or -1 for the calling partition
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : success EINVAL : Invalid Partition ID FH_ERR_INVALID_STATE : Partition state is invalid (not running)

11.1.2.10.3 FSL_HV_IOCTL_PARTITION_GET_STATUS

IOCTL code: FSL_HV_IOCTL_PARTITION_GET_STATUS

Description: Query the status of a partition

FSL_HV_IOCTL_PARTITION_GET_STATUS takes a **fsl_hv_ioctl_status** structure as an argument.

Table 538. FSL_HV_IOCTL_PARTITION_GET_STATUS fields

Parameter	Description
__u32 partition	An input parameter. Partition ID of the partition to query, or -1 for the calling partition
__u32 ret	An output parameter. Specifies the return value. Values are described below : 0 : success EINVAL : Invalid Partition ID
__u32 status	An output parameter. Returns the status of the partition. Returned Values for "status" : 0 = Stopped 1 = Running 2 = Starting 3 = Stopping

11.1.2.10.4 FSL_HV_IOCTL_PARTITION_START

IOCTL code: FSL_HV_IOCTL_PARTITION_START

Description: Start a (stopped) partition.

FSL_HV_IOCTL_PARTITION_START takes a fsl_hv_ioctl_start structure as an argument.

Table 539. FSL_HV_IOCTL_PARTITION_START fields

Parameter	Description
__u32 partition	An input parameter. Partition ID of partition to start
__u32 entry_point	An input parameter. The offset within the guest IMA to start execution
__u32 load	An input parameter. Flag identifying whether to load images or not.
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Invalid Partition ID EV_INVALID_STATE : Partition to start is not in stopped state.

11.1.2.10.5 FSL_HV_IOCTL_PARTITION_STOP

IOCTL code: FSL_HV_IOCTL_PARTITION_STOP

Description: Stop a running partition.

FSL_HV_IOCTL_PARTITION_STOP takes a fsl_hv_ioctl_stop structure as an argument.

Table 540. FSL_HV_IOCTL_PARTITION_STOP fields

Parameter	Description
__u32 partition	An input parameter. Partition ID of partition to start, or -1 for the calling partition.
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Invalid Partition ID FH_ERR_INVALID_STATE : Partition is not running or it is paused

11.1.2.10.6 FSL_HV_IOCTL_MEMCPY

IOCTL code: FSL_HV_IOCTL_PARTITION_MEMCPY

Description: Copy memory between partitions. Data is copied from the "source" partition to the "target" partition. Memory copying between two remote partitions or within the same partition is not supported.

FSL_HV_IOCTL_PARTITION_MEMCPY takes a fsl_hv_ioctl_memcpy structure as an argument.

Table 541. FSL_HV_IOCTL_PARTITION_MEMCPY fields

Parameter	Description
__u32 source	An input parameter. Partition ID of source partition, or -1 for the calling partition
__u32 target	An input parameter. Partition ID of target partition, or -1 for the calling partition
__u64 local_vaddr	An input parameter. User-space virtual address of a buffer in the "source" partition
__u64 remote_paddr	An output parameter. Guest physical address of the a buffer in the "target" partition. This buffer must be guest physically contiguous.
__u64 count	An input parameter. Number of bytes to copy. Both the source and target buffers must be at-least "count" bytes long.
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Source or Target Partition ID is invalid. EFAULT : Unable to map source or target buffer

IOCTL Return code:

Table 542. FSL_HV_IOCTL_PARTITION_MEMCPY return codes

Return value	Description
EINVAL	Memory copying between two remote partitions or within the same partition is not supported.
ENOMEM	Internal memory allocation failures
EACCES	Unable to lock source buffer

11.1.2.10.7 FSL_HV_IOCTL_DOORBELL

IOCTL code: FSL_HV_IOCTL_DOORBELL

Description: Ring a doorbell.

FSL_HV_IOCTL_DOORBELL takes a **fsl_hv_ioctl_doorbell** structure as an argument.

Table 543. FSL_HV_IOCTL_DOORBELLfields

Parameter	Description
__u32 doorbell	An input parameter. Handle of the doorbell to ring doorbell
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Invalid handle

11.1.2.10.8 FSL_HV_IOCTL_GETPROP

IOCTL code: FSL_HV_IOCTL_GETPROP

Description: Get a device tree property from another partition

FSL_HV_IOCTL_GETPROP takes a fsl_hv_ioctl_prop structure as an argument.

Table 544. FSL_HV_IOCTL_GETPROP fields

Parameter	Description
__u32 handle	An input parameter. Handle of partition whose tree to access
__u64 path	An input parameter. Virtual address of path name of node to access
__u64 propname	An input parameter. Virtual address of name of property to access
__u64 propval	An output parameter. Virtual address of property data buffer. The property value is returned in this parameter.
__u32 proplen	An input parameter. Size of property data buffer
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Invalid Partition handle ENOMEM : Internal memory allocation failures ERR_INVALID : Partition in boot stage EFAULT : Unable to access path or property name ENOENT : Invalid path or Property not found in partition device tree EV_BUFFER_OVERFLOW : Caller supplied buffer (propval) is too small

IOCTL Return code:

Table 545. FSL_HV_IOCTL_GETPROP return codes

Return value	Description
EINVAL	Property length larger than max. supported property length (32K)
ENOMEM	Internal memory allocation failures
ENAMETOOLONG	Path name or Property name too long

11.1.2.10.9 FSL_HV_IOCTL_SETPROP

IOCTL code: FSL_HV_IOCTL_SETPROP

Description: Set a device tree property in another partition

FSL_HV_IOCTL_SETPROP takes a fsl_hv_ioctl_prop structure as an argument.

Table 546. FSL_HV_IOCTL_SETPROP fields

Parameter	Description
__u32 handle	An input parameter. Handle of partition whose tree to access
__u64 path	An input parameter. Virtual address of path name of node to access
__u64 propname	An input parameter. Virtual address of name of property to access
__u64 propval	An input parameter. Virtual address of property data buffer
__u32 proplen	An input parameter. Size of property data buffer
__u32 ret	An output parameter. Specifies the return value. Values are described below: 0 : Success EINVAL : Invalid Partition handle EFAULT : Unable to access path or property name ENOMEM : Invalid path or Property could not be set ERR_INVALID : Partition in boot stage

IOCTL Return code:

Table 547. FSL_HV_IOCTL_SETPROP return codes

Return value	Description
EINVAL	Property length larger than max. supported property length (32K)
ENOMEM	Internal memory allocation failures
ENAMETOOLONG	Path name or Property name too long

11.1.2.11 Hypervisor Debug Stubs

11.1.2.11.1 Hypervisor debug stubs overview

This chapter specifies the interface for implementing a debug stub in the NXP Embedded Hypervisor.

In order to integrate into the hypervisor a debug stub must implement an initialization interface and register several callbacks.

The hypervisor provides API that enable a stub to do the following:

- Access guest memory by effective address
- Access guest memory by guest physical address
- Access guest registers for a virtual CPU (vcpu)—GPRs, FPRs, SPRs, PMRs, MSR, CR, PC

A NXP Embedded Hypervisor byte-channel must be configured in the guest device tree to provide and enable communications with a host debugger.

When a partition is configured to support debugging via a debug stub, the stub has full access to the physical CPU debug resources and guest is not permitted access to the debug resources.

11.1.2.11.2 Hypervisor-to-Stub Interfaces

11.1.2.11.2.1 Stub Per-CPU Data

The hypervisor maintains per-partition and per-virtual-CPU data structures that a debug stub may need to access. The data structures are declared in **include/percpu.h**.

- Per partition data:

```
typedef struct guest_t;
```

- Per virtual CPU data:

```
typedef struct gcpu;
```

A stub can get direct access to the virtual CPU data using the get_gcpu() function:

```
gcpu_t *gcpu = get_gcpu();
```

Within the gcpu_t struct a pointer field exists for use by a stub to maintain per virtual CPU private data.

```
void *dbgstub_cpu_data;
```

Within the gcpu_t struct a pointer exists to the debug stub's device tree configuration node:

```
dt_node_t *dbgstub_cfg;
```

Access to **per-partition** hypervisor data is accessible via a pointer in the `gcpu_t` structure.

```
guest_t *guest;
```

11.1.2.11.3 Hypervisor Registration of Debug Stubs

The hypervisor interfaces to a debug stub through a set of callbacks that a stub statically defines in a source file:

```
#include "stubops.h"

typedef struct {

        const char *compatible;

        void (*vcpu_init)(void);

        void (*vcpu_start)( trapframe_t *trapframe);

        void (*vcpu_stop)(void);

        int (*debug_interrupt)(trapframe_t *trapframe);

} stub_ops_t;} stub_ops_t;
```

The attr_debug_stub macro must be used when declaring the structure which will place the declaration in a special section by the linker so the hypervisor can find it.

Example:

```
#include "stubops.h"

static stub_ops_t attr_debug_stub stub_ops = {

        .compatible = "gdb-stub",

        .vcpu_init = gdb_stub_init,

        .vcpu_start = gdb_stub_start,

        .vcpu_stop = gdb_stub_stop,

        .debug_interrupt =  gdb_stub_process_trap,

};
```

The "compatible" field must be identical to the device tree compatible field in the node that declares the stub in the partition node of the hypervisor configuration device tree (see Debug Stub Node on page 2230 for additional details).

11.1.2.11.3.1 Callbacks

11.1.2.11.3.1.1 Call back context

All callbacks should only change hypervisor state through the APIs provided.

11.1.2.11.3.1.2 vcpu_init callback

Function prototype: void (*vcpu_init)(void);

The vcpu_init() function is called once for each virtual CPU during partition initialization..

The function performs tasks such as the following:

- initializing the stub byte-channel (see Byte-channel Registration on page 2257).
- configuration debug control registers (e.g. DBCR0[IDM])
- enable debug interrupts via MSR[DE]
- allocation of per-vcpu memory and setting the gcpu->dbgstub_cpu_data pointer

A pointer to the stub's device tree configuration node is available in gcpu->dbgstub_cfg.

11.1.2.11.3.1.3 vcpu_start callback

Function prototype: void (*vcpu_start)(trapframe_t *trapframe);

The vcpu_start() function is called every time a virtual CPU is started (including after partition reboots).

The function performs tasks such as the following:

- Register handlers for any byte-channels used.

Note: the registered byte-channel handlers will run on the physical CPU that manages the physical UART interrupt (e.g. CPU 0). The byte-channel handler should use the hypervisors internal event mechanism to signal events to other physical CPUs (see Hypervisor gevents on page 2256).

11.1.2.11.3.1.4 vcpu_stop callback

Function prototype: void (*vcpu_stop)(void);

The vcpu_stop() function is called for each virtual CPU in a partition when the CPU being stopped. The function should undo operations performed in vcpu_start()-e.g. deregister byte-channel callbacks.

11.1.2.11.3.1.5 debug_interrupt callback

Function prototype: int (*debug_interrupt)(trapframe_t *trapframe);

Stubs must implement a call back to be invoked for handling debug interrupts.

Return Value

The debug_interrupt() callback must return the value 0 if the callback handled the interrupt. If the reason for the interrupt could not be determined (i.e. the debug event was not targeted to this stub) the call be must return the value 1.

11.1.2.11.3.2 Build Time Configuration

Stubs need to be added to the hypervisor's build system via the Kconfig and a Makefile.

In the `Kconfig` file in the hypervisor source create a new config entry (see the existing GDB stub as an example).

In the file `Makefile.build` conditionally add the stub source file(s).

Example:

```
hv-src-$(CONFIG_GDB_STUB) += gdb-stub.c
```

11.1.2.12 Hypervisor APIs

This section describes the hypervisor APIs available to debug stubs and other custom code .

11.1.2.12.1 Trapframe

Many APIs require a trapframe_t pointer passed to them. A trapframe contains the current context of the guest. For debug stubs, the stub will receive a pointer to this structure when the stub's callback functions are invoked.

NOTE

The trapframe should be considered an opaque data structure and should not be accessed directly by stubs.

11.1.2.12.2 SPR access

For direct access to SPRs (e.g. debug registers) for internal use by the debug stub the mtspr() and mfspr() routines should be used.

Header file:

libos/io.h

Table 549. SPR access functions

Function	Description
void mtspr(int reg, register_t val)	writes a special purpose register
register_t mfspr(int reg)	reads a special purpose register

11.1.2.12.3 Guest Register access

Header file:

greg.h

Table 550. Guest Register access functions

Function	Description
int read_gspr(trapframe_t *regs, int spr, register_t *val)	Reads special purpose registers.
int write_gspr(trapframe_t *regs, int spr, register_t val)	Reads special purpose registers
int read_ggpr(trapframe_t *regs, int gpr, register_t *val)	Reads general purpose registers
int write_ggpr(trapframe_t *regs, int gpr, register_t val)	Reads general purpose registers
int read_gfpr(trapframe_t *regs, int gpr, register_t *val)	Reads floating point registers
int write_gfpr(trapframe_t *regs, int gpr, register_t val)	Reads floating point registers
void read_gmsr(trapframe_t *regs, register_t *val)	Reads the machine state register
void write_gmsr(trapframe_t *regs, register_t val, int as_guest)	Reads the machine state register.
void read_gcr(trapframe_t *regs, register_t *val)	Reads the condition register
void write_gcr(trapframe_t *regs, register_t val)	Reads the condition register
void read_gpc(trapframe_t *regs, register_t *val)	Reads the program counter
void write_gpc(trapframe_t *regs, register_t val)	Writes the program counter

Table continues on the next page...

Table 550. Guest Register access functions (continued)

Function	Description
int read_pmr(trapframe_t *regs, int pmr, register_t *val)	Reads a PMR (performance monitor register)
int write_pmr(trapframe_t *regs, int pmr, register_t val)	Writes a PMR (performance monitor register)

Table 551. Guest Register access function parameters

Parameter	Description
trapframe_t *regs	The trapframe of the current context.
int spr	The spr number
int gpr	The gpr number
register_t *val	A pointer to where the data being read should be placed-- a hypervisor effective address
register_t val	The data being written.
int as_guest	The **as_guest** parameter specifies whether the access is being done 'as a guest' or by the hypervisor for internal use. Value values are: 1 0 The value 1 should be used when a stub is making an MSR access on behalf of a host debugger which is debugging a **guest**. The value 0 should be used when the stub needs to write the MSR for its own private use, such as setting DE to enable debug interrupts.

Return values

The read_gspr, write_gspr, read_ggpr, write_ggpr, read_gfpr, and write_gfpr functions return an int.

Table 552. Guest Register access return values

Return Code	Description
0	The operation succeeded
non-zero	an invalid argument was passed (e.g. bad register number)

11.1.2.12.4 Memory access

11.1.2.12.4.1 By Guest Effective Address

APIs to access a guest's virtual memory are provided. These functions assume the current context of the guest—i.e. the LPID, PID, and AS (address space).

Header file:

guestmemio.h

Table 553. By Guest Effective Address functions

Function	Description
static inline void guestmem_set_data(trapframe_t *regs)	Must be called for accessing **data**. Sets the address space context for subsequent guestmem_in/out calls.
static inline void guestmem_set_insn(trapframe_t *regs)	Must be called for accessing **instructions**. Sets the address space context for subsequent guestmem_in/out calls.
int guestmem_in32(uint32_t *ptr, uint32_t *val)	Reads 32-bits of data
int guestmem_in8(uint8_t *ptr, uint8_t *val)	Reads 8-bits of data
int guestmem_out32(uint32_t *ptr, uint32_t val)	Writes 32-bits of data
int guestmem_out8(uint8_t *ptr, uint8_t val)	Writes 8-bits of data
int guestmem_icache_block_sync(char *ptr)	Should be called for modifications to instructions. For the cache block corresponding to the effective address of ptr, flushes the data cache and invalidate the icache.

Table 554. By Guest Effective Address function parameters

Parameter	Description
trapframe_t *regs	The trapframe of the current context.
uint32_t *ptr uint8_t *ptr	The guest effective address where the memory access is to be made
uint8_t *val uint32_t *val	A pointer to where the data being read should be placed—a hypervisor effective address
uint8_t val uint32_t val	The data being written

Return values

The guestmem_in32, guestmem_in8, guestmem_out32, and guestmem_out8, functions return an int with the following meaning:

Table 555. By Guest Effective Address return values

Return Code	Description
GUESTMEM_OK	The operation succeeded
GUESTMEM_TLBMISS	A TLB miss/error occurred
GUESTMEM_DSI	A data storage interrupt occurred

NOTE

For access to virtual addresses other than the current context a stub may use the external PID load/store facilities of the CPU.

11.1.2.12.4.2 By Guest Physical Addresses

Functions are available to access a guest memory by guest physical address. The API handles setting up a temporary TLB mapping for the access.

Header file:

paging.h

Table 556. By Guest Physical Addresses functions

Function	Description
size_t copy_to_gphys(pte_t *tbl, phys_addr_t dest, void *src, size_t len int cache_sync)	Write guest memory using a guest physical address. Returns the number of bytes successfully copied.
size_t copy_from_gphys(pte_t *tbl, void *dest, phys_addr_t src, size_t len)	Read guest memory using a guest physical address. Returns the number of bytes successfully copied.

Table 557. By Guest Physical Addresses function parameters

Parameter	Description
pte_t *tbl	Pointer to the guest physical page table. This pointer is available in the per-virtual CPU data structure e.g. get_gcpu()->guest->gphys
phys_addr_t dest	Guest physical address to copy to
phys_addr_t src	Guest physical address to copy from
phys_addr_t addr	Guest physical address to map
void *src	Hypervisor effective address to copy from

Table continues on the next page...

Table 557. By Guest Physical Addresses function parameters (continued)

Parameter	Description
void *dest	Hypervisor effective address to copy to
int cache_sync	If non zero causes the i-cache to be synchronized. Will flush the data cache and invalidate the icache for the range of addresses written. This flag should be used when writing instructions.

Function	Description
void *map_gphys(int tlbentry, pte_t *tbl, phys_addr_t addr, void *vpage, size_t *len, int maxtsize, register_t mas2flags, int write)	Temporarily map guest physical memory into a hypervisor virtual address. Returns the hypervisor effective address of the mapping. If the region being mapped is not accessible to the guest the return value is NULL. The mapping is temporary and does not need to be cleared.

Parameter	Description
int tlbentry	A temporary TLB index. Must be the value TEMPTLB1 or TEMPTLB2
pte_t *tbl	Pointer to the guest physical page table. This pointer is available in the per-virtual CPU data structure e.g. get_gcpu()->guest->gphys
phys_addr_t addr	Guest physical address to map
void *vpage	virtual base of window to hold mapping. Use the virtual address that the hypervisor has initialized in temp_mapping[].
size_t *len	number of bytes to map
int maxtsize	maxtsize tsize of the virtual window
register_t mas2flags	MMU assist register 2 flags which specify whether the mapping is memory or I/O. Value values are: TLB_MAS2_IO TLB_MAS2_MEM
int write	if non-zero, fail if write access is not allowed

Example:

```
vdest = map_gphys(TEMPTLB1, tbl, dest, temp_mapping[0],
                  &chunk, TLB_TSIZE_16M, 1);
```

11.1.2.12.5 Guest TLB Search

The guest TLBs can be searched using the following API which works in a manner very similar to the **tlbsx** instruction.

Header file:

`tlb.h`

Table 558. Guest TLB Search functions

Function	Description
`int guest_tlb_search(phys_addr_t ea,` `int as, int pid, tlb_entry_t *mas);`	Searches the guest TLB with the lookup controlled by the effective address in **ea**, the address space specified in **as**, and the process id specified in *pid*. The function returns the values of mas0, mas1, mas2, mas3, and mas7 as defined by the e500 architecture.

Table 559. Guest TLB Search function parameters

Parameter	Description
uintptr_t ea	The effective address to search for.
int as	The address space to search in-valid values are 0 and 1
int pid	The process ID to search for
mas_regs_t *mas	Pointer to a struct containing the MMU assist register values.

Data from this API is returned in the tlb_entry_t struct, the address of which is passed in the call. The values of the The mas_regs_t struct is defined as:

```
typedef struct mas_regs {
    register_t mas0;
    register_t mas1;
    register_t mas2;
    register_t mas3;
    register_t mas7;
} tlb_entry_t;
```

The values of the mas register fields is identical to that of the physical CPU. See the e500 specific core reference manual for details.

Return values

A return value of 0 indicates the function complete without error. A non-zero value indicates an error occurred

11.1.2.12.6 Reading Guest TLBs

The guest_tlb_read() API provides a mechanism by which a stub can iterate over and read the TLBs for a vcpu.

The TLBSEL field in mas0 selects which TLB is being read.

Header file:

tlb.h

Table 560. Reading Guest TLBs functions

Function	Description
int guest_tlb_read(tlb_entry_t *mas, uint32_t *flags)	Iterates over and reads entries from a guest TLB. A **mas** struct is passed as an argument and the TLB to be read is selected by setting the TLBSEL bit in the mas0 field. To start an iteration sequence the flags argument must have the TLB_READ_FIRST bit set.

Table 561. Reading Guest TLBs function parameters

Parameter	Description
mas_regs_t *mas	A pointer to a guest_mas_t structure which contains the fields read from the TLB entry. The encoding is identical to the MAS registers defined in the hardware architecture Refer to the Core Reference Manual for the specific encoding of each MAS register. The TLB to be read is selected by setting the TLBSEL bit in the mas0 field. Note: between iterations of invoking this API the values in the 'gmas' struct must not be changed.
uint32_t *flags	An in/out parameter. A bitmask of flags to the API as described below: **Flag**: TLB_READ_FIRST **Description**: Specifies that the first TLB entry shall be returned, regardless of the state of the *mas* struct. This flag is self clearing.

Table 562. Reading Guest TLBs return values

Return value	Description
0	success
ERR_NOTFOUND	There are no more TLB entries to be read.

A return value of 0 indicates the function complete without error. A non-zero value indicates an error occurred

11.1.2.12.7 CCSR space access

Stubs can get direct access to the CCSR region the stub must get a base address by mapping the region using the map() API. However, note, this allows the stub access to all the CCSR region, not just the portion allocated to the partition. To restrict accesses to only the regions accessible to the partition use the guest physical access methods (see By Guest Physical Addresses on page 2249).

11.1.2.12.7.1 CCSR Map

Header file:

paging.h

Table 563. map functions

Function	Description
void *map(phys_addr_t paddr, size_t len, int mas2flags, int mas3flags)	Given a physical address, create a permanent hypervisor mapping.

Table 564. map function parameters

Parameter	Description
phys_addr_t paddr	paddr base of physical region to map
size_t len	len length of region to map
int mas2flags	mas2flags WIMGE bits
int mas3flags	mas3flags permission bits

Return values

returns the virtual address of the mapping, or NULL if out of resources

11.1.2.12.7.2 get_ccsr_phys_addr

Header file:

hv.h

Table 565. get_ccsr_phys_addr functions

Function	Description
phys_addr_t get_ccsr_phys_addr(size_t *ccsr_size)	get the CCSR physical address from the device tree

Table 566. get_ccsr_phys_addr function parameters

Parameter	Description
phys_addr_t paddr	paddr base of physical region to map
size_t len	len length of region to map
int mas2flags	mas2flags WIMGE bits
int mas3flags	mas3flags permission bits
size_t *ccsr_size	if not NULL is the returned size of CCSR, in bytes

Return values

returns the physical address of CCSR space, or NULL if there was an error

11.1.2.12.7.3 Example

```
          size_t ccsr_size;
          phys_addr_t ccsr_pa = get_ccsr_phys_addr(&ccsr_size);
          uint32_t *ccsr_va = map(ccsr_pa, ccsr_size, TLB_MAS2_IO,
TLB_MAS3_KERN);
```

11.1.2.12.8 I/O space access functions

A stub may access memory mapped I/O space using IO functions defined in **libos/include/libos/io.h**

Table 567. I/O space access functions

Function	Description
static inline uint8_t in8(const uint8_t *ptr);	Reads 8-bits of data from memory mapped I/O space
static inline uint16_t in16(const uint16_t *ptr);	Reads 16-bits of data from memory mapped I/O space
static inline uint32_t in32(const uint32_t *ptr);	Reads32-bits of data from memory mapped I/O space
static inline out8(const uint8_t *ptr, uint8_t val);	Writes 8-bits of data to memory mapped I/O space
static inline out16(const uint16_t *ptr, uint16_t val);	Writes 16-bits of data to memory mapped I/O space
static inline out32(const uint32_t *ptr, uint32_t val);	Writes 32-bits of data to memory mapped I/O space

11.1.2.12.9 Virtual CPU sleep state

An API is provided for a debug stub to query the sleep state of a virtual CPU. A vcpu can be running, in an idle state, or in a nap state.

Header file:

hv.h

Table 568. Virtual CPU sleep state functions

Function	Description
int get_vcpu_state(guest_t *guest, unsigned int vcpu)	get the sleep state of the specified vcpu

Table 569. Virtual CPU sleep state function parameters

Parameter	Description
guest_t *guest	pointer to the guest structure
unsigned int vcpu	Virtual CPU number to query

Return values

Value returned is one of the following:

```
FH_VCPU_RUN

FH_VCPU_IDLE

FH_VCPU_NAP
```

11.1.2.12.10 Restart a Partition

The current partition (which the stub is debugging) can be restarted via the restart_guest() API.

Header file:

hv.h

Table 570. Restart a Partition functions

Function	Description
void restart_guest(guest_t *guest)	Restarts the current partition.

Any hypervisor loaded images are automatically loaded on a partition restart. To prevent this, set the guest_t no_auto_load field to 1.

Table 571. Restart a Partition function parameters

Parameter	Description
guest_t *guest	Pointer to the guest structure.

11.1.2.12.11 Memory Allocation

For private dynamic memory allocation, stubs have access to a standard set of C memory allocation routines such as malloc() and free().

Refer to the **libos/include/libos/malloc.h** include file for a full description of these interfaces.

11.1.2.12.12 Device trees

11.1.2.12.12.1 Device Trees Overview

Three conceptual device trees exist in the NXP Embedded Hypervisor architecture that may be of interest to a debug stub or a debug stub: 1) the hardware device tree, 2) the hypervisor configuration tree, 3) guest device trees.

The hardware device tree is an ePAPR-compliant provided by boot firmware (u-boot) and simply describes the hardware of the system. The hardware device tree is accessible by a global variable (declared in init.c):

```
dt_node_t *hw_devtree;
```

The hypervisor configuration blob describes the configuration of the hypervisor and all partitions. See the NXP Embedded Hypervisor specification for complete details. The configuration device tree is accessible by a global variable (declared in init.c):

```
dt_node_t *config_tree;
```

Each partition has its own guest device tree. The guest device tree is the view of hardware and virtual resources as seen by guest software. This is accessible via pointer in the guest_t structure.

```
struct dt_node *devtree;
```

All the device trees can be accessed and parsed using hypervisor routines (see include/devtree.h).

11.1.2.12.12.2 Stub Node in the Hypervisor Configuration Tree

To have a byte-channel communications mechanism, a byte-channel must be defined for each debug stub and the association between CPUs and byte-channel numbers must be specified in the partition node defining the partition in the hypervisor configuration tree (see Debug Stub Node on page 2230 for details).

11.1.2.12.13 Hypervisor gevents

The hypervisor provides a mechanism for event signaling that enables one component to signal another component (including across physical CPUs) referred to as a gevent. A gevent uses an event number and a callback to run when the gevent is signaled.

An gevent handler function must have the following prototype:

```
void function_name(trapframe_t *regs)
```

Gevents handlers are registered with the register_gevent() API. The gevent handler will always run with the trapframe_t pointing to the guest context. The interrupt context of the handler is that of external interrupts, meaning that external interrupts are disabled (MSR[EE]=0. When the handler returns it will return to the guest (unless other gevents or interrupts were pending).

A common example for using gevents for a debug stub is to handle received data on a byte-channel. When data is received on a debug stub's byte-channel, a stub-defined receive-data callback is usually invoked. This callback runs in the context of the critical interrupt on the CPU that received the UART interrupt. However the debug stub consuming data from the bytechannel may be running on a different physical CPU. The gevent mechanism can be used to invoke to invoke the main loop of the debug stub on a different CPU as if the exception came from the guest—i.e. the trapframe is a guest trapframe.

Signaling Events

To signal an event use the setgevent() routine.

Table 572. Signaling Events functions

Function	Description
int register_gevent(eventfp_t handler)	Register a gevent handler. Return value is the gevent number.
void setgevent(gcpu_t *gcpu, int event)	Send an event to a target CPU. Parameters are a pointer to the target gcpu_t struct and the event number.

Table 573. Signaling Events function parameters

Parameter	Description
gcpu_t *gcpu	Pointer to the gcpu structure.
int event	Gevent number

11.1.2.12.14 Byte-channels

11.1.2.12.14.1 Byte-channel Registration

A debug stub is responsible for initializing its byte-channel communications channel. This must be done once per virtual CPU and normally would be done in the vcpu_init() callback.

Header file:

```
byte_chan.h
```

Table 574. Byte-channel Registration functions

Function	Description
int init_byte_channel(dt_node_t *node)	Given a pointer to the stub's configuration node initializes the byte-channel. Return value 0 - the function completed normally 1 - an internal error occurred If the function is successful node->bch contains the handle of the byte-channel. If this field is NULL the init_byte_channel() API failed.

The byte_chan_handle_t structure set by init_byte_channel() contains a send and receive queue which can configured with callbacks.

To define a callback for data received, set the data_avail field in the queue structure. The optional consumer field can specify private data to be passed to the callback.

To define a callback when space is available in the queue, set the space_avail field in the queue structure. The optional producer field can specify private data to be passed to the callback.

Example

```
vcpu_init callback:
 init_byte_channel(stub->node);

                if (!stub->node->bch) {

                        printlog(LOGTYPE_DEBUG_STUB, LOGLEVEL_ERROR,

                                 "%s: gdb stub byte chan allocation failed\n",

                                 __func__);

                        return;

                }
vcpu_start callback:
/* register the callbacks */

                stub->node->bch->rx->consumer = gcpu;

                smp_lwsync();

                stub->node->bch->rx->data_avail = rx;
```

In the example below, a receive callback for a byte-channel sends an event indicating that data is received.

```
        /** Callback for data received

         */

        static void rx_callback(queue_t *q)

        {

                setgevent((gcpu_t*)q->consumer, GEV_GDB);

        }
```

11.1.2.12.14.2 Byte-channel Send/Receive of Data

Routines are available to send and receive data on a byte-channel.

Table 575. Byte-channel Send/Receive of Data functions

Function	Description

ssize_t byte_chan_send(byte_chan_handle_t *bc, const uint8_t *buf, size_t len)	Given a handle to a byte-channel, send a buffer of character data.
	Parameters
	`bc // handle to the byte-channel to use`
	`buf // the buffer to send`
	`len // the number of bytes to send`
	Return value
	The number of bytes sent

ssize_t byte_chan_receive(byte_chan_handle_t *bc, uint8_t *buf, size_t len)	Given a handle to a byte-channel, receive a buffer of character data.
	Parameters
	`bc // handle to the byte-channel to use`
	`buf // the buffer to fill with data`
	`len // the size of the buffer`
	Return value
	The number of bytes received

size_t queue_get_avail(const queue_t *q)	Returns the number of available byte of data in the queue
size_t queue_get_space(const queue_t *q)	Returns the amount of available space (in bytes) in the queue

Example:

To see how many bytes of data are available on the receive queue of a byte-channel

```
        count = queue_get_avail(bc->rx);
```

11.1.2.13 Hypervisor customization

11.1.2.13.1 Hypervisor Customization Overview

In addition to the creation of debug stubs, the APIs defined in can also be used to implement custom modifications to the hypervisor for several uses described in this section.

11.1.2.13.2 Custom Reset

The hypervisor implements a system reset function that can be accessed by privileged partitions via an hcall (see FH_SYSTEM_RESET on page 2186). By default the hypervisor implementation simply write the SOC's Global Utilities reset control register to initiate a hardware reset request.

The hypervisor's reset function can be overridden by a custom implementation of a function with the following prototype (defined in **include/guts.h**):

```
int system_reset(void);
```

The implementation should take any system-specific steps that are necessary to reset the system. If the reset occurs normally, the function will never return. If **system_reset** fails for any reason, the function must return a non-zero return value.

A new source file can be added to the hypervisor by adding a line to the **Makefile.build** hypervisor source file: :

Example:

```
hv-src-y += my_reset.c
```

Any custom code added to the hypervisor should only used documented interfaces (see Hypervisor APIs on page 2245).

11.1.2.13.3 System Health Monitor

The hypervisor implements a watchdog timer to detect severe system failures that require a system reset. The hypervisor watchdog interrupt executes a customizable system health monitor routine that can periodically monitor system specific conditions to determine whether the system is in a healthy state.

The hypervisor's default stub implementation of the system health check function can be overridden by implementing a function with the following prototype (defined in **include/timers.h**):

int system_health_check(void);

The implementation should take any system-specific steps that are necessary to monitor and determine the health of the system. If the system is determine to be healthy, a value of zero must be returned. If the system needs to be reset a non-zero value must be returned.

A new source file can be added to the hypervisor by adding a line to the Makefile.build hypervisor source file:

Example:

hv-src-y += my_sys_health_check.c

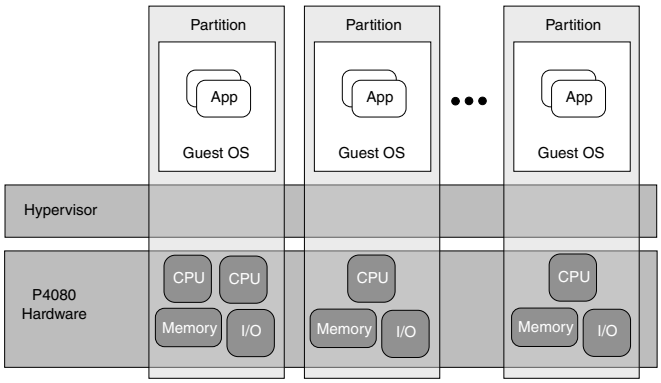
Any custom code added to the hypervisor should only used documented interfaces (see Hypervisor APIs on page 2245).

11.1.3 Embedded Hypervisor Software User Manual

11.1.3.1 Introduction

This document describes how to create partitioned systems using the NXP Embedded Hypervisor software. The architecture of the hypervisor is described in the *NXP Embedded Hypervisor Software Reference Manual* [2].

The NXP Embedded Hypervisor is a layer of software that enables the efficient and secure partitioning of a multi-core system. A system's CPUs, memory, and I/O devices can be divided into logical groupings or *partitions*. Each partition is capable of executing a guest operating system.



Key features of the hypervisor software architecture are summarized below—

- Partitioning. Support for partitioning of CPUs, memory, and I/O devices:
  - CPUs. Each partition is assigned one or more CPU cores.
  - Memory. Each partition has a private memory region that is only accessible to the partition that is assigned the memory. In addition, shared memory regions can be created and shared among multiple partitions.
  - I/O devices. SoC I/O devices may be assigned directly to a partition (direct I/O), making the device a private resource of the partition, and providing optimal performance.
- Protection and Isolation. The hypervisor provides complete isolation of partitions, so that one partition cannot access the private resources of another. The SoC PAMU (an IOMMU) is managed by the hypervisor to ensure device-to-memory accesses are constrained to allowed memory regions only.
- Sharing. Mechanisms are provided to selectively enable partitions to share certain hardware resources (such as memory).
- Virtualization. Support for mechanisms that enable the sharing of certain devices among partitions such as the system interrupt controller.
- Performance. The hypervisor software uses the features of the NXP Embedded Hypervisor APU (see reference []) to provide security and isolation with very low overhead. Guest operating systems take external interrupts directly without hypervisor involvement providing very low interrupt latency.
- Ease of migration. The hypervisor uses a combination full emulation and para-virtualization to maintain high performance and requiring minimal guest OS changes when migrating code from a physical CPU to the hypervisor.

Refer to the reference manual [2] for a detailed description of the hypervisor software architecture including a description of virtual CPUs, hypercall services, and device tree properties.

A high-level understanding of the **power.org** *ePAPR* [1] specification (and device trees) is a pre-requisite for understanding the content of this document. The hypervisor adopts the device tree and multi-core boot architecture of the ePAPR. In ePAPR terminology, the hypervisor is a *client program* of the boot firmware (e.g. u-boot). It also is a *boot program* in its role of booting partitions.

A device tree is data structure that represents system hardware. It consists of nodes arranged in a tree structure with each node having properties/value pairs. CPUs, memory, and I/O devices are represented by nodes. Refer to the ePAPR for a description of device trees.

11.1.3.1.1 Hypervisor Software Architecture Overview

The NXP Embedded Hypervisor provides the capability to create partitions in which guest software can in isolation without the possibility of interference from other partitions in the system.

The software architecture consists of several key components:

- Virtual CPU (vcpu)—Software executing in a partition sees a view of the CPU core that is nearly identical to the physical CPU, except for some CPU state which is hypervisor privileged and not accessible. The reference manual [2] describes the virtual CPU in detail
- Hypercall services—Some services are provided via hypercalls, including: the interrupt controller, byte-channels, inter-partition doorbells, IOMMUs, and partition management. Hypercalls are like system calls where guest software can make explicit requests for services to the hypervisor.
- Boot services—The hypervisor adopts the device tree and multicore boot architecture of the power.org ePAPR specification. This defines mechanisms for resource discovery within a partition and for starting multiple CPUs in a single partition.
- Debug services—Guest software with a debug stub can use the stub without change through the capabilities of the vcpu. In addition, the hypervisor provides a gdb stub in the hypervisor that provides an interface for a host debugger to use to debug guest operating systems.
- Direct I/O—high speed peripherals are not virtualized and are assigned and managed directly by partitions. External interrupts are taken by partitions directly with no hypervisor involvement.

11.1.3.1.3 Conventions used in the Examples

Many of the examples in this document use *device tree syntax* to express device trees. This syntax is defined in the ePAPR [1].

In device trees property values that are numbers (e.g. addresses) are expressed in terms of cells (each cell being a 32-bit value). For the examples in this document the assumption is that unless otherwise stated that device tree nodes are in a context where *#address-cells* and *#size-cells* both have a value of 2-i.e. addresses are expressed as 64-bit values. See the ePAPR for information about the *#address-cells* and *#size-cells* properties.

11.1.3.2 Partitioning a system with embedded hypervisor software

11.1.3.2.1 Hypervisor boot overview

11.1.3.2.1.1 Hypervisor Boot Sequence

The hypervisor must be booted with an ePAPR compliant boot program such as u-boot. The boot program initialization includes the following:

- Probing and initialization DDR memory
- Configuring the physical memory map of the system (sets up Local Access Windows (LAWs for memory and I/O regions)
- Enabling caches
- Configuring clocks
- Allocating and programming certain hardware identifiers (e.g. cache stash ids, logical I/O device numbers)
- Loading the hypervisor program image into memory (e.g. from flash)
- Creating a spin table as specified by the ePAPR to facilitate multi-cpu boot.
- Releasing all secondary CPUs from reset and set them spinning in the spin table
- Configuring the *hardware device tree* and loading it into memory with the *bootargs* property on the */chosen* node set to specify the address of the hypervisor configuration tree
- Transferring control to the hypervisor program image on the boot cpu

As part of its initialization the hypervisor releases all secondary CPUs from the spin table set up by the boot program. The hypervisor then initializes each partition and boots guest operating systems as per each partition's configuration (see Guest boot overview on page 2264).

11.1.3.2.1.2 Device Tree Overview

A device tree is a tree-based data structure defined by the ePAPR [1] which describes resources available to an operating system. When the control is passed to the operating system a pointer to the device tree is passed.

Device trees are developed in a text format referred to as "device tree syntax" or DTS. These text DTS files are compiled into a binary form referred to as "device tree blob" or DTB. An open source tool, DTC, is available to do this compilation.

11.1.3.2.1.3 Hardware Device Trees, Configuration Trees, and Guest Device Trees

The hypervisor will be passed an ePAPR-compliant "hardware device tree" (from u-boot) when it is booted that describes all the hardware in the system.

A separate tree of configuration information is loaded into memory by the boot program with its address passed to the hypervisor using the *bootargs* property of the hardware device tree's /chosen node. This configuration information is referred as the "hypervisor configuration tree", and it contains all hypervisor configuration parameters and partition definition information. Based on the configuration tree, the hypervisor will create partitions. The hypervisor dynamically creates ePAPR-compliant guest device trees for each partition. A guest device tree describes the resources available to the partition including —CPUs, memory, I/O devices, and other virtual resources.

See below—u-boot copies the hardware device tree and configuration tree into hypervisor memory. The hypervisor places a guest device tree in the memory of each guest.

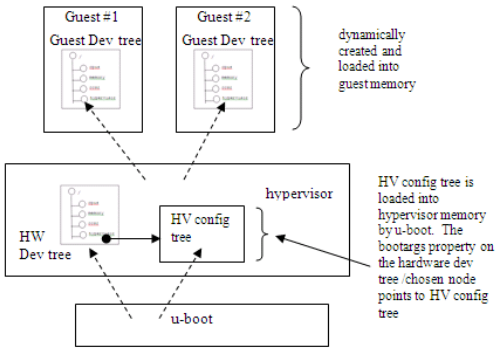

Figure 352.

Hypervisor configuration trees are described in detail in Partitioning a system on page 2265.

11.1.3.2.2 Guest boot overview

11.1.3.2.2.1 Guest Boot Sequence

The hypervisor uses the hardware device tree and the configuration tree as input to create and instantiate all partitions. The hypervisor does the following to boot a partition:

- Does internal housekeeping to instantiate and create the partition. This includes configuring the PAMUs for the devices owned by the partition.
- Creates a guest device tree and copies it into the partition's memory
- Loads all images into the partition's memory as specified by the *load-image-table, guest-image*, and *linux-rootfs* properties.
- Creates an ePAPR compliant spin table and sets the cpu node's *status, enable-method*, and *release-addr*
- Initializes the virtual CPU as per the requirements of the ePAPR
- Transfers control to the entry point of the guest operating system on the boot cpu for that partition

NOTE

Note: some partitions may not have their images loaded and be started by the hypervisor. A usage model is also supported where a single partition can be initially started which manages other partitions, including loading images and starting them.

11.1.3.2.2.2 Guest Device Trees

The device tree which is passed from the hypervisor to the guests is referred to as a *guest device tree*. This device tree describes 1) the hardware resources (cpu, memory, I/O devices) available to the partition, 2) virtual resources available to a partition (e.g. virtual mpic, byte-channels), and 3) partition configuration properties (e.g. partition name). See the reference manual [2] for details.

11.1.3.2.3 Guest Physical Addresses

Guest software executing in a partition sees a physical address space created by the hypervisor that may not directly correspond to physical addresses in the system hardware. System hardware addresses are referred to in this document as **true** *physical addresses*. The addresses in the guest's physical address space are referred to as **guest** *physical addresses*. For example, there may be multiple partitions, each with memory at guest physical address 0x0—where within each partition, address 0x0 corresponds to a unique *true* physical address (see the example in the figure below).

In the definition of a partition, physical memory regions can be assigned to the partition and the guest physical to true physical mapping can be specified (see *guest physical memory areas* in [2]). The hypervisor maintains this mapping in a manner that is completely transparent to guest software. Guest software is made aware of the *guest* physical address ranges available to it via the guest device tree passed to the partition at initialization.

Guest software has no knowledge of and has no means to determine true physical addresses. DMA transactions are programmed by guest software in terms of guest physical addresses.

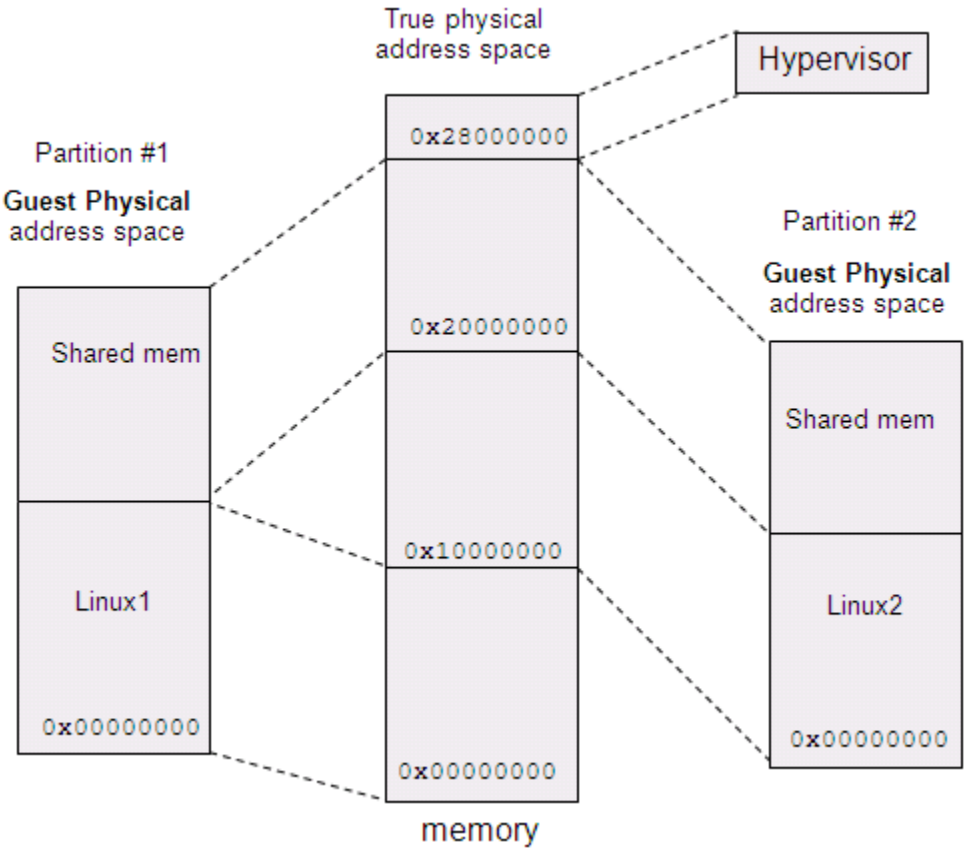

Figure 353. guest physical and true physical addresses

In the above example, partition #1 has 256 MB of private memory at guest physical 0x0, which also maps to true physical 0x0.

Partition #2 has 256 MB of private memory at guest physical 0x0 that corresponds to true physical 0x10000000.

The partitions share a 128 MB region of shared memory that is located at true physical 0x20000000. Both partitions see that shared memory at guest physical 0x10000000.

11.1.3.3 Partitioning a system

This section describes the key aspects of defining a partition in the hypervisor configuration tree.

The hypervisor configuration tree is physically a device tree, but is in a custom form for hypervisor use only and is not ePAPR compliant.

The hypervisor configuration tree defines all configurable parameters and all partitions:

- Physical memory areas (PMAs)—specify how physical memory is partitioned
- DMA windows—a definition of regions to which DMA devices are allowed to access
- General hypervisor configuration parameters, including:

  - The memory region reserved for private hypervisor use
  - The physical devices assigned to the hypervisor
  - Hypervisor console configuration
- Byte-channel mux—the declaration of any byte-channel multiplexers
- Doorbells—a declaration of all doorbells
- Partition definition—each partition has a partition node that specifies properties of the partition
  - Assignment of physical CPUs to a partition
  - List of guest physical memory areas (each referencing a physical memory area)
  - Device nodes—a set of nodes which assign I/O devices and portals to a partition. For DMA-capable devices the node describes which DMA window table the device should use
  - Image loading properties—the location of any images to be loaded by the hypervisor
  - Guest address where the device tree should be placed
  - Doorbells assigned to the partition
  - Byte-channels—a table that defines all byte-channels in the partition and the UART or mux endpoints each is attached to
  - Guest aliases
  - Modifications to the guest device tree such as the guest's /chosen node

11.1.3.3.1 Configuration Tree Structure

The hypervisor configuration tree is represented as a device tree as described by the ePAPR. However, it does not describe hardware and is not ePAPR compliant. It is specifically designed for hypervisor configuration.

All addresses in the configuration tree are 64-bits and thus consist of two cells.

The root node of the configuration tree must contain a compatible property that identifies the device tree as a hypervisor configuration tree:

Example:

```
/dts-v1/;
/{
compatible = "fsl,hv-config";

// contents go here

};
```

When the hypervisor is booted by boot firmware it must be passed the address of the configuration tree in the bootargs property of the */chosen* node in the **hardware** device tree.

The bootargs property must include the following value: config-addr=[physical address of blob]

Example:

```
chosen {
     bootargs = "config-addr=0x00400000";
};
```

11.1.3.3.2 Partitioning memory

11.1.3.3.2.1 Physical Memory Areas

A key aspect of partitioning a system is to partition the system's physical memory. To do this physical memory is divided into *physical memory areas* (or PMAs). PMAs are statically defined by the system architect and cannot be changed dynamically in a running system. The hypervisor itself is also assigned a PMA for its internal use.

PMAs are defined in terms of **true physical** addresses.

When a partition is defined, *guest physical memory areas* (or GPMAs) are created which define references to the specific PMAs that are to be assigned to the partition. The GPMA defines the **guest physical** address at which the memory is seen in the partition's guest physical address map.

A partition-private memory region is defined by assigning a PMA to only a single partition. Shared memory regions (between partitions) can easily be created by simply assigning the same PMA to multiple partitions.

PMAs have several constraints:

- Size must be a power of 2
- Must be size aligned

The L3/CPC (Corenet platform cache) by default is shared by all PMAs—i.e. memory transactions to **any** memory address allocate in the CPC. The CPC supports a feature by which ways of the cache can be removed from the default set of ways allocated from and can be partitioned for private or shared use by certain PMAs.

Example

Table 576. PMA example

PMA	True physical address	Size	CPC ways to allocate to (default is all)	Comment
pma0	0x00000000	128MB		hypervisor
pma1	0x08000000	128MB		p2
pma2	0x10000000	256MB		p1
pma3	0x20000000	64MB		p3
pma4	0x60000000	64MB	30,31	shared, heap

Example

Below is an example of "pma0" and "pma4" (from table above) being defined in the hypervisor configuration tree. The "pma4" node specifies that ways 30 and 31 of the platform cache are allocated for pma4 and not for other PMAs.

```
pma0 {
    compatible = "phys-mem-area";
    addr = <0x0 0x00000000>;
    size = <0x0 0x08000000>;  // 128MB
};

pma4 {
    compatible = "phys-mem-area";
    addr = <0x0 0x60000000>;
    size = <0x0 0x04000000>;  // 64MB
```

```
                    allocate-cpc-ways = <30 31>;
                };
```

NOTE

The hypervisor uses the coherence subdomain feature of the QorIQ SoC to implement PMAs. This allows cache coherency snoop traffic in the system to be restricted to only the physical CPUs that actually access the memory. There are a limited number of coherence subdomains supported by the SoC hardware and thus only up to 28 PMA are supported with the full coherence subdomain support.

More than 28 PMAs are supported, but memory accesses would be snooped by all CPUs.

11.1.3.3.2.2 Shared Memory

As described in the section above, sharing memory between partitions is accomplished by assigning the same PMA to multiple partitions.

11.1.3.3.2.3 DMA Windows

The SoC's IOMMU (PAMU or *Peripheral Access Management Unit*) requires careful configuration to specify the allowable regions of memory that can be targeted by DMA-capable devices. Guest software specifies **guest physical** addresses when programming a device to do DMA. The PAMU (configured by the hypervisor) handles the translation of guest physical addresses to true physical. This translation of addresses is transparent to guest software.

PAMU supports defining power-of-two memory sized DMA windows which can be optionally be sub-divided into a power-of-two number of sub-windows. Please consult the chip specific Reference Manual for the maximum number of supported sub-windows. The sub-windows enable the definition of address regions that can be the target of DMA operations where the regions may be discontiguous in guest physical address space or true physical address space.

In the context of the hypervisor, a *DMA window* is conceptually a table of guest physical memory regions that are the valid targets of a DMA operation. Each row of the table consists of a guest physical address and size.

A DMA window describes a particular configuration of guest address space and may be applicable to one or more partitions.

Each DMA-capable I/O device must reference one DMA window.

Single Region DMA Window

If the DMA region being defined is a single contiguous region of memory a single DMA window can be defined. The DMA window is a table with one row defining the region.

Example 3-1, Single Contiguous Region

Example—window specifying one 256MB region

	Guest Physical	Size
0	0x00000000	256MB

The DMA window represented above would look like this in the hypervisor configuration tree:

```
        window0 {
            compatible = "dma-window";
            guest-addr = <0x0 0x00000000>;
            size = <0x0 0x10000000>; // 256 MB
        };
```

DMA Windows for Discontiguous Address Regions

If multiple, discontiguous address regions (whether with respect to the guest physical or true physical address spaces) are needed, DMA sub-windows are used to represent and configure the regions. In this case, the DMA window is conceptually a table with power-of-two rows, with each row defining one sub-window. There are several key parameters in defining sub-windows that need to be understood:

- **Total size**. This is the total size of the address space that may be the target of DMA-encompassing all address regions. This must be a power of 2. See the *size* property of dma-window node.
- **Base address**. This is the guest physical address at which the overall DMA region starts. This must be size aligned with the total size. See the *guest-address* property of dma-window node.
- **Sub-window count**. The number of sub-windows must be a power-of-two. Please consult the chip Reference Manual for the maximum number of supported sub-windows. Note, that this simply defines how many subwindows the total size is divided into. It does not specify the number of **valid** subwindows. See *subwindow-count* property of dma-window node.
- **Maximum sub-window size**. The maximum size of each sub-window is computed by: total-size / sub-window-count.
- **Sub-window starting address**. Each sub-window starts at an address computed by:

```
overall-starting-address + (sub-window index * maximum-sub-window-size)
```

- **Sub-window size**. Each sub-window can specify a size that may be smaller than the maximum sub-window size.

Example 3-1, Two address regions—Contiguous with respect to guest physical and discontiguous with respect to true physical

A partition has 128MB of memory at guest physical address 0x0, composed of two 64MB memory regions that are discontiguous with respect to true physical.

	Guest Physical	True Physical	Size
0	0x00000000	0x64000000	64MB
1	0x04000000	0x54000000	64MB

Below is a valid set of parameter for specifying this configuration.

Total size: 0x08000000 (128MB)

Base address: 0x00000000

Sub-window count: 2

Maximum sub-window size: 64MB

Sub-window starting address:

- For sub-window 0: 0x0
- For sub-window 1: 0x04000000

Sub-window size: 64MB for both sub-windows

The DMA window represented in would look like this in the hypervisor configuration tree:

```
        window1 {
                compatible = "dma-window";
                guest-addr = <0x0 0x00000000>;  // base address
                size = <0x00000000 0x08000000>; // 128MB
                subwindow-count = <2>;
```

```
                sub-window@0 {
                    compatible = "dma-subwindow";
                    guest-addr = <0x0 0x00000000>;
                    size = <0x0 0x04000000>; // 64 MB
                };
                sub-window@1 {
                    compatible = "dma-subwindow";
                    guest-addr = <0x0 0x04000000>;
                    size = <0x0 0x04000000>; // 64 MB
                };
        };
```

Example 3-2, Two address regions discontiguous with respect to both guest physical and true physical

A partition has 64MB of memory at guest physical address 0x0 and 64MB at 0x60000000. Both are the targets of DMA. The shaded rows in the table below show the discontiguous regions that are the valid destinations of DMA. The other sub-windows but are not defined since they are not valid DMA targets.

	Guest Physical	Size
0	0x00000000	64MB
1	0x10000000	-
2	0x20000000	-
3	0x30000000	-
4	0x40000000	-
5	0x50000000	-
6	0x60000000	64MB
7	0x70000000	-

Below is a valid set of parameter for specifying this configuration.

Total size: 0x80000000 (2 GB)

Base address: 0x00000000

Sub-window count: 8

Maximum sub-window size: 256MB

Sub-window starting address:

- For sub-window 0: 0x0
- For sub-window 6: 0x60000000

Sub-window size: 64MB for both sub-windows

The DMA window represented in would look like this in the hypervisor configuration tree:

```
        window1 {
                compatible = "dma-window";
                guest-addr = <0x0 0x00000000>;  // base address
                size = <0x00000000 0x80000000>; // 2GB
```

```
                subwindow-count = <8>;
                sub-window@0 {
                    compatible = "dma-subwindow";
                    guest-addr = <0x0 0x00000000>;
                    size = <0x0 0x04000000>; // 64 MB
                };
                sub-window@6 {
                    compatible = "dma-subwindow";
                    guest-addr = <0x0 0x60000000>;
                    size = <0x0 0x04000000>; // 64 MB
                };
        };
```

DMA Windows for Message Signaled Interrupts

PCI Express message signaled interrupts are generated by PCI devices writing to a interrupt controller register which causes the MSI. This register access must go through the PAMU like any other memory transaction, and thus a DMA subwindow must be defined for MSIs. Refer to the pcie-msi-subwindow property in the reference manual [2] for details.

DMA Windows for RapidIO

SRIO maintenance transactions are translated into regular memory accesses to the CCSR space and must be authorized by PAMU, and thus a DMA subwindow must be defined for such accesses. Refer to the *srio-ccsr-subwindow* property in the reference manual [2] for details.

Example 3-3 , DMA window for RapidIO

In the example below, a partition has 512MB of memory and support SRIO maintenance transactions, which requires a DMA window covering both memory and CCSR space. Memory is at guest physical 0x0 (0x70000000 true physical) and CCSR space is at 0xf_fe0000000. The first two sub-windows are used to map the guest regular memory and the last one is used to map the CCSR space.

NOTE

Note: A DMA window to cover the entire guest space is needed because the RapidIO uses the same LIODN for both maintenance transactions (which are accesses into the CCSR space) and general transactions (which are accesses in regular guest memory).

Sub-win index	Guest Physical	True Physical	Size
0	0x0_00000000	0x0_70000000	256M
1	0x0_10000000	0x0_80000000	256M
255	0xf_f0000000	0xf_f0000000	256M

Below is a valid set of parameter for specifying this configuration.

Total size: 0x1_000000000 (64GB)

Base address: 0x00000000

Sub-window count: 256

Maximum sub-window size: 256MB

Sub-window starting address:

- For sub-window 0: 0x0
- For sub-window 1: 0x0_100000000

- For sub-window 255: 0xf_f0000000

Sub-window size: 256MB for each sub-window

The DMA window represented in would look like this in the hypervisor configuration tree:

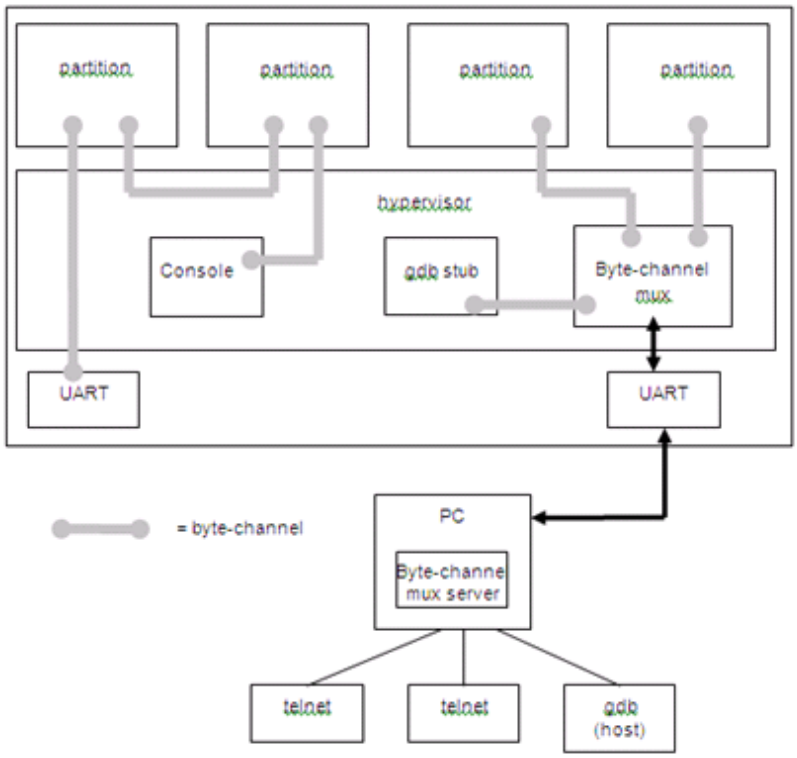
```
dw_srio: dw_srio {
        // DMA window for part1_linux
            compatible = "dma-window";
            guest-addr = <0 0>;
            size = <0x10 0x0>; //64GB
            subwindow-count = <256>;
            sub-window@0 {
                compatible = "dma-subwindow";
                guest-addr = <0 0>;
                size = <0x0 0x10000000>;
            };
            sub-window@1 {
                compatible = "dma-subwindow";
                guest-addr = <0x0 0x10000000>;
                size = <0x0 0x10000000>;
            };
            sub-window-ccsr@2 {
                compatible = "dma-subwindow";
                guest-addr = <0xf 0xf0000000>;
                size = <0x0 0x10000000>;
                srio-ccsr-subwindow;
            };
        };
```

11.1.3.3.3 Byte-channel Multiplexers and Byte-channels

Each partition created by hypervisor can have multiple byte-channel ports which provide a virtualized interrupt-driven character-based I/O channel connected to one of several endpoints:

- A physical UART
- Another byte-channel
- A byte-channel multiplexer (mux)
- A hypervisor GDB stub
- The hypervisor console

A byte-channel multiplexer (mux) multiplexes multiple byte-channels over a single physical link to a host computer, running a mux server which demultiplexes the streams of data.



A byte-channel mux is defined by creating a global node (parent is root) in the configuration device tree that specifies which serial node the mux is attached to.

Partitions that define a byte-channel attached to the mux can then reference the phandle to this node.

The endpoint property specified in the mux node must reference a hypervisor owned UART node.

11.1.3.3.4 Example

In the example below a byte-channel mux is defined. The endpoint value of <&serial1> refers to a physical serial port node that is assigned to the hypervisor.

```
uartmux: uartmux {
        compatible = "byte-channel-mux";
        endpoint = <&serial1>;
};
```

11.1.3.3.5 Doorbells

The hypervisor provides a doorbell mechanism that enables one partition to signal other partitions. This is a one-way signal with no payload which results in an external interrupt (IVOR4) in the destination partition. The interrupt is gated off of MSR[EE].

Flexible configuration of send and receive endpoints are provided. Inter-partition doorbell send and receive endpoints can be configured in any combination of one-to-one, one-to-many, many-to-one, or many-to-many.

A partition is aware of the doorbell endpoints (send or receive) available to it through its device tree which contains a node for each doorbell endpoint.

A doorbell send is done via an hcall.

The partition with the receive endpoint can configure which CPU within the partition receives the doorbell via the hypervisor's VMPIC services.

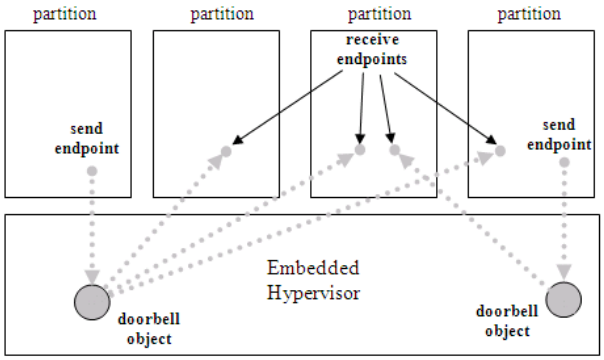


Figure 354. Doorbell connection example

A doorbell is defined by specifying a node (*compatible* = "doorbell") in the configuration device. This node is then referenced by partitions that want send and/or receive endpoints associated with that doorbell object.

11.1.3.3.5.1 Example—Doorbell Configuration

The example below shows the hypervisor configuration tree definition for a doorbell node that is referenced by three partitions —a send endpoint in partition #1, and receive endpoints in partitions #2 and #3. The definition of endpoints is described in Inter-partition Doorbell Configuration on page 2290.

```
doorbells {
        dbell0: doorbell0 {
                compatible = "doorbell";
        };
};

// Partition 1
part1 {
        compatible = "partition";
        ...
        doorbell0_send {
                compatible = "send-doorbell";
                global-doorbell = <&dbell0>;
        };
        ...
};

// Partition 2
part2 {
        compatible = "partition";
        ...
        doorbell0_recv {
                compatible = "receive-doorbell";
                global-doorbell = <&dbell0>;
        };
        ...
};

// Partition 3
part2 {
        compatible = "partition";
```

```
                ...
                doorbell0_recv {
                    compatible = "receive-doorbell";
                    global-doorbell = <&dbell0>;
                };
                ...
        };
```

11.1.3.3.6 Guest device tree node updates

The hypervisor uses the hardware device tree and the hypervisor configuration tree to create partitions and dynamically create guest device trees for the partitions. A "node update" mechanism is provided that allows a system architect to specify a set of directives to customize how the nodes in the guest device tree will look.

Some examples where this feature may be useful:

- adding a new property to a node originating from the hardware device tree
- deleting an unwanted subnode from a sub tree originating from the hardware device tree
- appending the compatible property of a doorbell node with a string that explicitly defines the purpose of the node
- defining a new subtree of nodes that specify custom configuration information

Updates are specified in a node with the name *node-update*. The properties of the *node-update* node specify the directives over the creation of nodes in the guest device tree.

Except for the special property names listed below, all properties under *node-update* will be copied exactly as is to the guest device tree. If the property already exists in the node it will be replaced. Note: phandle references will not be resolved for properties with phandle value. See the *node-update-phandle* node (see How to set the /chosen node for a Partition on page 2276) for node updates to properties with phandle values.

In addition to copying properties, the following special properties have special meaning:

- delete-prop
- delete-node
- delete-subnodes
- prepend-stringlist

Please refer to the *Embedded Hypervisor Software Reference Manual* [] for additional details on the *node-update* properties.

The following nodes in the hypervisor configuration tree support node-update nodes:

- Device nodes
- Doorbell nodes
- Byte-channel nodes
- Partition nodes
- Guest physical memory area nodes

The *node-update* node supports updates to descendants of the node which the node-update modifies. Updates to descendants can be done by replicating the node hierarchy under the *node-update* node using the names of the descendant nodes.

Note: phandles and phandle references in *node-update* nodes are not supported—use a *node-update-phandle* node (see How to set the /chosen node for a Partition on page 2276).

11.1.3.3.6.1 Example: node-update

Suppose a hardware device tree looked like the following:

```
stuff {
        foo@0 {
            reg = <4>;
            bar@10000 {
                    reg = <5>;
            };
        };
};
```

In a hypervisor configuration tree device node, to assign the "/stuff" node to the partition and add a *compatible* property to the "bar" node and delete the *reg* property, the *node-update* node could look like this:

```
stuff {
        device = “/stuff”
        node-update {
                foo@0 {
                    bar@10000 {
                        compatible = “xyz,mystuff”;
                        delete-prop = “reg”;
                    };
                };
        };
};
```

The resulting guest device tree would look like:

```
stuff {
        foo@0 {
                reg = <4>;
                bar@10000 {
                        compatible = “xyz,mystuff”;
                };
        };
};
```

11.1.3.3.6.2 How to set the /chosen node for a Partition

The /chosen node is a special device tree node defined by the ePAPR that may be used to pass configuration parameters to an operating system. In order to set the /chosen node for a partition, use *node-update* on the partition node.

Example

```
node-update {
    chosen {
        linux,stdout-path = "/serial2";
        bootargs = "console=ttyS0,115200";
    };
};
```

11.1.3.3.6.3 node-update-phandle

To support the creation or update of properties that reference other nodes using phandle values a special node with the name *node-update-phandle* is supported. If one property references another node by phandle both properties **must** be assigned to the partition.

Each property listed under *node-update-phandle* has a property name with a value that specifies the phandle of the referenced node in the configuration device tree.

Please refer to the *Embedded Hypervisor Software Reference Manual* [] for additional details on the *node-update-phandle* properties.

11.1.3.3.6.4 Example: node-update-phandle

In the example below a *node-update-phandle* property is used to create a new property with a value consisting of an array of phandles to other nodes from the hardware device tree assigned to this partition.

Configuration Tree

```
partition1 {
    ...
    qman-portalA {
            device = "/qman-portals@f4200000/qman-portal@0";
            vcpu = <0>;

            node-update-phandle {
            fsl,qman-pool-channels = <&qman-pool@1 &qman-pool@2>;
            };
    ...
    qman-pool@1 {
            device = "/qman-portals/qman-pool@1";
    };
    qman-pool@2 {
            device = "/qman-portals/qman-pool@2";
    };
};
```

Guest Device Tree

The guest device tree reflects the node-update-phandle being processed—the fsl,qman-pool-channels property has two phandles corresponding to the nodes being referenced.

```
...
qman-portal@24000 {
    cell-index = <0x9>;
    compatible = "fsl,p4080-qman-portal", "fsl,qman-portal";
    ...
    fsl,qman-pool-channels = <99 100>;
    ...
};
...
qpool1: qman-pool@1 {
    cell-index = <1>;
    compatible = "fsl,p4080-qman-pool-channel", "fsl,qman-pool-channel";
    fsl,qman-channel-id = <0x21>;
    phandle = <99>;
};
qpool2: qman-pool@2 {
```

```
            cell-index = <2>;
            compatible = "fsl,p4080-qman-pool-channel", "fsl,qman-pool-channel";
            fsl,qman-channel-id = <0x22>;
            phandle = <100>;
        };
        ...
```

11.1.3.3.7 Partition definition

A partition is defined by declaring a "partition node" in the configuration device tree. At a minimum a partition definition must define the following:

- one CPU
- one region of physical memory (a "guest physical memory area")
- the location where the guest device tree is to be loaded

Beyond those minimum requirements, the following may be defined:

- additional CPUs
- a label string (for use by partition management tools)
- additional memory regions
- assignment of physical I/O devices to the partition
- a specification of any images to be loaded by the hypervisor before starting the partition
- the assignment of virtual resources to the partition (byte-channels, doorbells endpoints)
- debug stub configuration
- node-update and node-update-phandle nodes that specify modifications to the guest device tree.

A partition node has a *compatible* value of "partition".

Example

Below the definition of a simple partition is shown. The partition contains two CPUs, one memory region, and one I/O device (a UART).

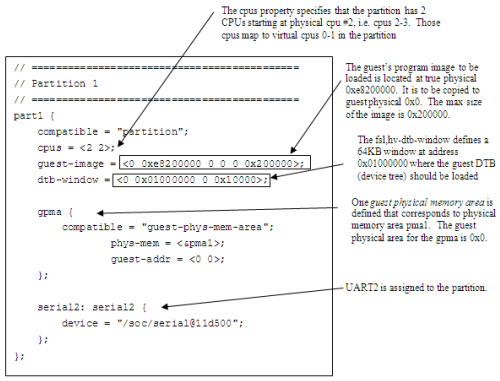

Figure 355.

11.1.3.3.7.1 Assigning CPUs to Partitions

Each physical CPU in the system may be assigned to a partition. The physical CPU assigned to a partition is enumerated logically in the guest device tree. In the guest device tree reg property and the unit address reflect the virtual CPUs index within the partition.

The example below defines two virtual cpus (virtual CPU 0 and 1) that map to physical CPUs 6 and 7.

Example:

```
cpus = <6 2>; // 2 cpus starting at CPU #6
```

On multi-threaded cores (e.g. e6500 dual-threaded core) the hardware threads are individually assigned to the partitions. The hypervisor will expose the vcpu to guests as a single threaded core. As a consequence, it's possible to have two partitions running on the same core but on distinct threads.

Example:

Given this hardware device tree snippet defining two dual-threaded e6500 cores:

```
PowerPC,e6500@0 {
        [...]
        reg = <0 1>;
        [...]
};

PowerPC,e6500@1 {
        [...]
        reg = <2 3>;
        [...]
};
```

this is how one assigns the first three hardware threads to a partition:

```
cpus = <0 3>;
```

The hypervisor will transparently expose three single-threaded e6500 cores to the partition.

11.1.3.3.7.2 Specifying the guest device tree address

The hypervisor creates a guest device tree in a partitions memory before the partition is started. The guest physical address where the DTB should be placed is specified in the *dtb-window* property. The format of the value of *dtb-window* is {guest physical address , size}.

Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for additional details.

Example:

```
dtb-window = <0 0x01000000 0 0x10000>;
```

11.1.3.3.7.3 Specifying a label

A label property can be used to specify an identifying string to name the partition. This string will be displayed when managing the partition.

Example:

```
label = "linux-p2";
```

11.1.3.3.7.4 Loading Images

The hypervisor can load guest images into a partition prior to starting it. Three properties can be used to specify these images.

- **guest-image**—the *guest-image* property specifies the source address, destination address, and size of an image to be executed when a partition is started. The following image types are supported:

- ELF (Executable and Linking Format)—the entry point into the image is calculated from the offset between **e_entry** and the **p_vaddr** field of the program header that contains **e_entry**. If the destination address equals -1, the physical address specified in the ELF program headers (**p_paddr** field) will be used as the destination guest physical address.
- uImage (u-boot Image format)—the entry point into the image is calculated from the offset between the load address and entry point.
- Binary. For binary images, offset 0x0 in the image is treated as the entry point.

- **linux-rootfs**—the linux-rootfs property specifies the source/destination addresses and size of Linux root filesystem. The following image types are supported: 1) uImage (u-boot Image format), 2) binary.

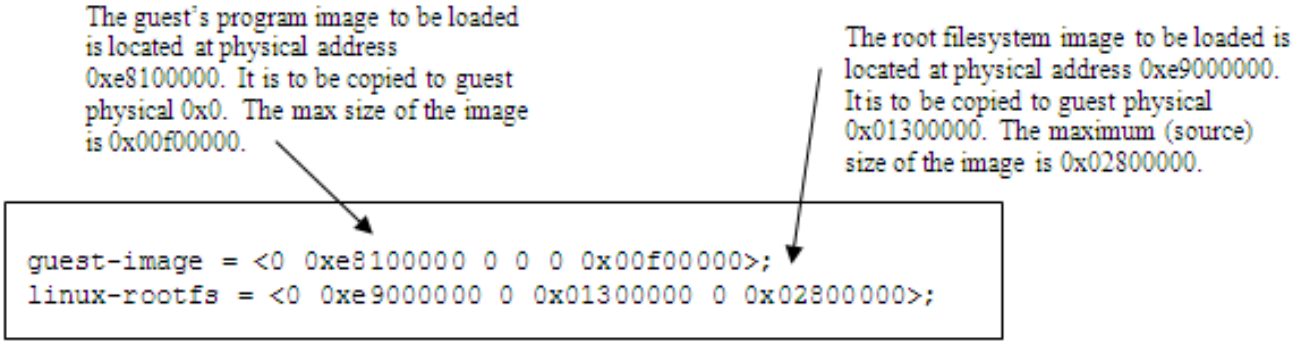
In the guest device tree for this partition, the *linux,initrd-start* and *linux,initrd-end* properties will be set in the /chosen node to reflect the start and end of the rootfs image as guest physical addresses.

- **load-image-table**—specifies the source/destination addresses and size of one or more supplementary images to be loaded by the hypervisor prior to partition start. The value is a prop-encoded array and is a table with one or more rows. The following image types are supported: 1) ELF (Executable and Linking Format), 2) uImage (u-boot Image format), 3) binary.

For ELF files, if the destination address equals -1, the physical address specified in the ELF program headers will be used as the destination guest physical address.

Source addresses are true physical. Destination addresses are guest physical. Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for additional details.

Example



Note, it is not required that the hypervisor load all images. At least 1 "manager" partition must be loaded and started by the hypervisor. The manager partition can then load images from its filesystem and start the managed partition. See Managed Partitions on page 2291.

11.1.3.3.7.5 Guest cache lock mode

By default guest software is permitted to lock lines in the CPU and platform caches. "Guest cache lock mode" can be disabled by specifying the *guest-cache-lock-disable* property on the partition node. This prevents guest software running in the partition from normally executing cache locking instructions (**dcbtls, dcbtstls, dcblc, icbtls, icblc**).

Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for additional details.

11.1.3.3.7.6 Guest debug mode

By default the CPUs debug resources (debug interrupt, IACx, DACx, DBCRx) are owned by the the partition. "Guest debug mode" can be disabled by specifying the guest-debug-disable property on the partition node.

Disabling guest debug mode is required in order to use hypervisor debug stubs for debugging guest operating systems (see Debug stub node on page 2294).

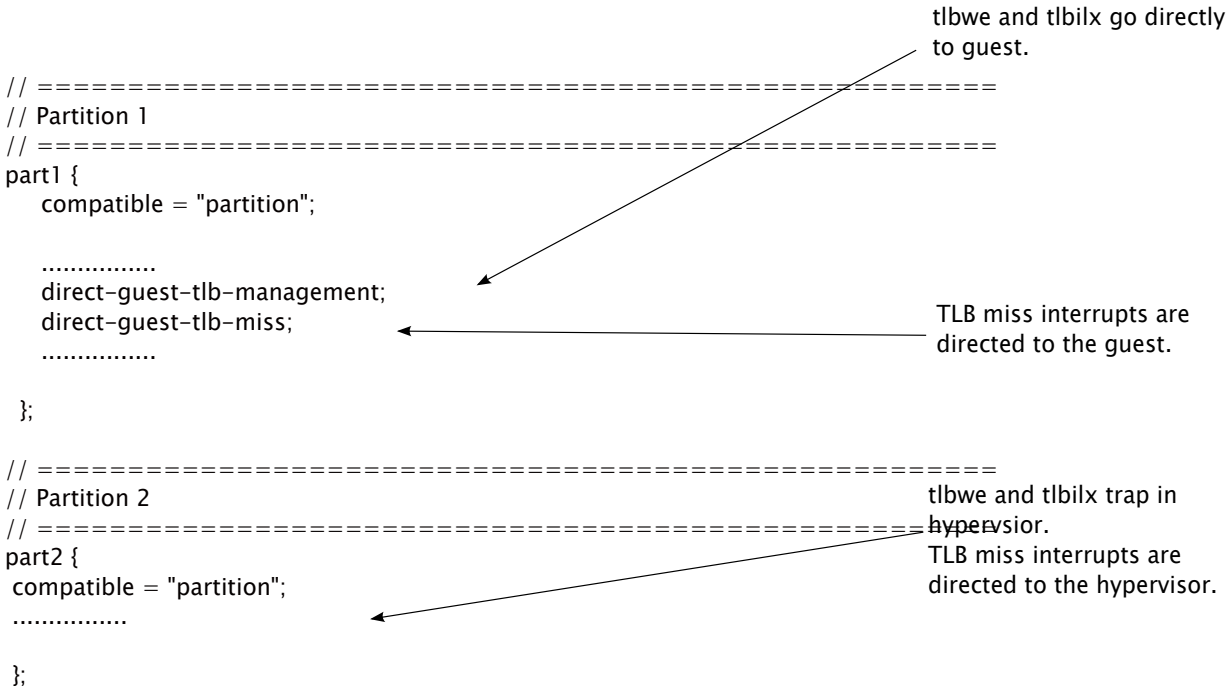
Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for additional details.

11.1.3.3.7.7 Guest TLB Management

e6500 core allows guest TLB management instructions. Two partition configuration options can be used in various combinations:

- direct-guest-tlb-management
- direct-guest-tlb-miss

Please refer to *Embedded Hypervisor Software Reference Manual* [2] for additional details.



11.1.3.3.7.8 Assigning Memory to Partitions

Memory is granted to partitions using "guest physical memory areas" (or GPMAs). GPMAs are defined as child nodes of a partition node. Each GPMA references a PMA (see Physical Memory Areas on page 2267). The GPMA also specifies the guest physical address at which the memory region should be located. A GPMA appears in the guest device tree as a standard ePAPR-compliant memory node.

Memory can be shared between 2 partitions by each partition creating a GPMA that references the same PMA.

Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for additional details.

Example 3-3, guest physical memory area

Hypervisor configuration tree:

```
        partition0 {
                ...
                gpma0 {
                        compatible = "guest-phys-mem-area";
                        pma = <&pma2>;  // 256MB region
                        guest-addr = <0 0>;
                };
                gpma1 {
                        compatible = "guest-phys-mem-area";
```

```
                        pma = <&pma8>;  // 64MB region
                        guest-addr = <0 0x64000000>;
                        node-update {
                            delete-prop = “device-type”;
                            prepend-stringlist = “compatible”,
                                            “fsl,shared-heap”;
                        };
                };
                ...
    };
```

Guest device tree as seen by partition 0:

```
    / {
            #address-cells = <2>;
            #size-cells = <2>;
            ...
            memory@0x0 {
                    device-type = "memory";
                    reg = <0x0 0x0 0x0 0x10000000>;
            };
            memory@0x64000000 {
                    compatible = “fsl,shared-heap”;
                    reg = <0x0 0x64000000 0x0 0x04000000>;
            };
            ...
    };
```

11.1.3.3.7.9 Assigning I/O devices to partitions

I/O devices are granted to partitions with a special "device node" which is a child of the partition node. Device nodes specify a path or alias (see the /aliases node in the ePAPR) in the hardware device tree to the I/O device being assigned.

The assigned device's hardware device tree nodes are copied under the node /devices in the guest device tree.

The hardware device tree expresses the true physical addresses of the system hardware. By default the hypervisor maintains a 1:1 (identity) mapping between true physical and guest physical addresses for all I/O devices.

There are 2 general types of devices represented by device nodes:

- a device that does no DMA (e.g. UART)
- DMA devices—a device that is capable of doing DMA (e.g. DMA controller). Every device that performs DMA expresses a logical I/O device number (LIODN) that the platform IOMMU (PAMU) uses to authorize the access. Certain devices which express multiple LIODNs have special characteristics in the configuration tree.

11.1.3.3.7.9.1 Standard Devices

Standard devices simply have a property that specifies the full path or alias to the node in the hardware device tree that represents the device being assigned to the partition.

Below the assignment of a device in the configuration tree is shown followed by what the node would look like in the guest device tree.

Partition configuration tree:

```
    partition0 {
        ...
        uart2 {
            device = "/soc/serial@11d500";   // serial2
```

```
        };
    };
```

Guest device tree:

```
    uart2 {
        cell-index = <0x2>;
        device_type = "serial";
        compatible = "ns16550";
        reg = <0 0xfe11d500 0 0x100>;
        clock-frequency = <0xe4e1c0>;
        interrupts = <0 0x2>;
        interrupt-parent = <0x564d5043>;
    };
```

11.1.3.3.7.9.2 DMA Devices

DMA devices require an additional property (*dma-window*) to specify the DMA window (see section) which is the guest physical memory regions which this device is allowed to access.

Example:

```
    fman0 {
        device = "fman0";
        dma-window = <&window0>;
     };
```

11.1.3.3.7.9.3 Queue Manager Portals

Qman portals are represented in the hardware device tree with a node containing a compatible value of "fsl,qman-portal." Qman portals express six different logical devices:

- Fman0
- Fman1
- SEC
- PME
- Dequeue data or context stashing
- Dequeue DQRR stashing

Qman portals are typically associated with physical CPUs, and thus a normal configuration would assign one Qman portal to a partition per physical CPU assigned to the partition.

There are 2 components involved in assigning Qman portal devices to a partition:

1. Definition of a *portal-devices* node.

   The portal-devices node configures the Fman0, Fman1, SEC, and PME logical devices. This single configuration is common for all portals within the partition.

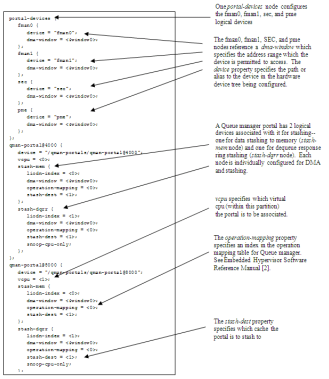
2. Qman portal device assignment node for each portal

Each Qman portal to be assigned is assigned using a device assignment node. In addition, the data/context stashing and DQRR stashing logical devices are configured in these nodes.

Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for a complete definition of all properties related to Qman portal assignment. The example below illustrates how the properties are used.

Example 3-4

Example of the assignment of two queue manager portals to a two CPU partition:



11.1.3.3.7.9.4 Bus types supported

The hypervisor supports partitioning of I/O devices in the hardware device tree that reside on the busses with the following compatible types:

- "simple-bus"
- "fsl,dpaa"

Simple Bus. For device nodes where all ancestors contain a compatible value of "simple-bus", and where no ancestor has been assigned to the partition, the hypervisor copies the node from the hardware device tree node to the guest tree under the node */devices*. Any *reg* property which may have contained an address offset is updated to reflect the full physical address of the devices registers as mapped by any *ranges* properties in the ancestry of the node. Any *ranges* property and unit addresses are also updated to reflect the full physical address.

fsl,dpaa. For device nodes with a parent that contains a compatible value of "fsl,dpaa", both the node and parent are copied to the guest device tree under the node */devices*.

11.1.3.3.7.9.5 ranges

The *ranges* property in an ePAPR-compliant hardware device tree describes the address mapping of a memory-mapped bus. It provides a means of defining a mapping or translation between the physical address space of the bus (the child address space) and the physical address space of the bus node's parent (the parent address space). See the ePAPR for additional information.

When assigning a bus node to a partition, unless the node defines a *map-ranges* property, the hypervisor will not assign the guest physical address regions defined by the *ranges* property to the partition (unless they are also referenced by the *reg* property of the node)

See the example below.

Example

A PCI bus is being assigned to a partition. The PCI memory address space is visible to guest software at 0x80000000 and is 512MB in size (as per the hardware device tree). Fragments of a configuration device tree and hardware device tree are shown below.

Configuration device tree:

```
        pci-e {
            device = "/soc/pcie@fe200000";
```

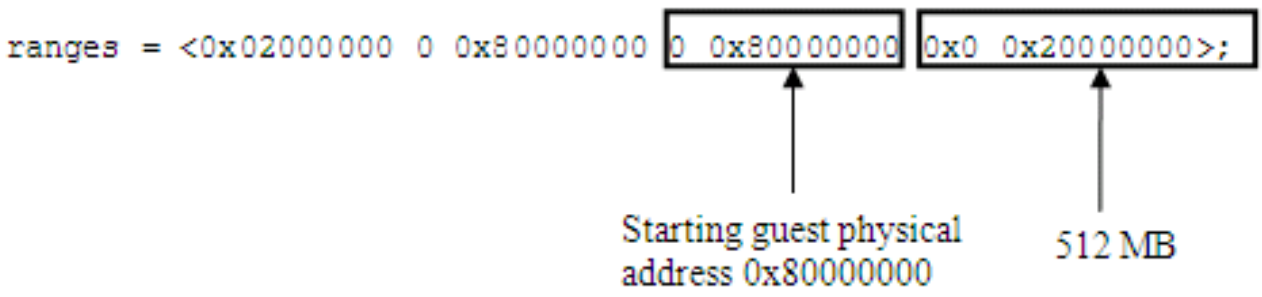
```
            map-ranges;
        };
```

Hardware device tree:

```
        / {
                compatible = "fsl,hv-platform-p4080", "simple-bus";
                model = "fsl,hv-linux-p1";
                epapr-version = "ePAPR-1.0";
                #address-cells = <2>;
                #size-cells = <2>;

                pci0: pcie@fe200000 {
                        cell-index = <0>;
                        compatible = "fsl,p4080-pcie", "fsl,mpc8548-pcie";
                        device_type = "pci";
                        #interrupt-cells = <1>;
                        #size-cells = <2>;
                        #address-cells = <3>;
                        reg = <0 0xfe200000 0 0x1000>;
                        bus-range = <0x0 0xff>;
                        ranges = <0x02000000 0 0x80000000 0 0x80000000 0x0 0x20000000>;
                        clock-frequency = <33333333>;
                        interrupt-parent = <&mpic>;
                        interrupts = <24 2>;
        };
```

In the example above, the PCI bus is assigned to the partition with the "pci-e" node. The map-ranges property specifies that hypervisor should treat the defined address ranges in the parent bus's address space as part of the valid guest address space. So in the example, a 512MB region at guest physical 0x80000000 will be treated by the hypervisor as a valid guest physical address. See figure below.



11.1.3.3.7.9.6 Propagation to Descendants

Certain properties of device nodes are applicable to descendants of the device in the hardware device tree to which the device node refers. The *dma-window* property applies to all descendants of the device in the hardware device tree.

Example:

```
        fman0 {
            device = "/soc@fe000000/fman@400000";
            dma-window = <&window2>;
        };
```

In the above example, the dma-window property applies to all child nodes of fman0 that are capable of DMA.

This behavior can be overridden for descendants of the base device by specifying a separate device node for the child node.

Example:

Suppose you want a different dma window for the fman0_rx2 child node of fman0. A separate device node for fman0_rx2 overrides the dma window specified in fman0.

```
fman0 {
        device = "/soc@fe000000/fman@400000";
        dma-window = <&window2>;
};
fman0_rx2 {
        device = "/soc@fe000000/fman@400000/port@8a000";
        dma-window = <&window3>;
};
```

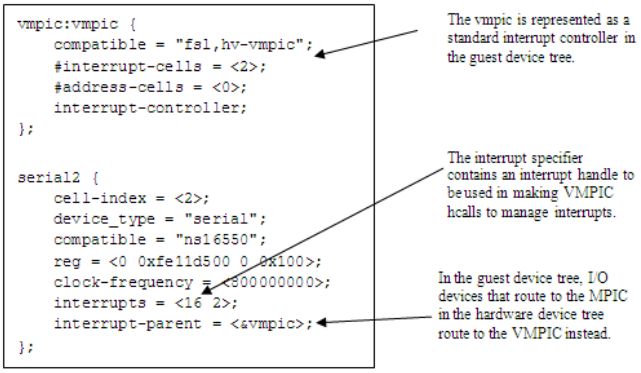
11.1.3.3.7.10 Interrupts and the VMPIC node

External interrupts are processed by guest software executing in a partition with a processing model similar to the hardware platform MPIC (Multiprocessor Programmable Interrupt Controller), with the exception that that MPIC hardware is not directly accessible by guest software. Instead, a virtual MPIC (VMPIC) interface provides interrupt controller services and is accessed via a hypercall interface. See the hypervisor reference manual [2] for a further detail about interrupt processing and the interrupt controller hypercall interface.

All hardware interrupts that route to the MPIC node (as described by the *interrupt-parent* property) in the hardware device tree will instead route to a VMPIC node in the guest device tree. Nodes with the VMPIC as an interrupt parent have interrupt specifiers that contain hypervisor- assigned interrupt numbers that are used as handles in VMPIC hcalls.

Example

Below is an example of a guest device tree that has a UART assigned to it.



Direct EOI—The hypervisor provides an optional mechanism by which in some circumstances an end-of-interrupt can be performed with no hypercall. See the mpic-direct-eoi property in the reference manual [2].

Message signaled interrupts—processing PCI Express MSIs has some special considerations. See the section on PCI Express and Message Signaled Interrupts in the reference manual [2].

NOTE

Hardware interrupts may not be shared between guest OSes or between the hypervisor and a guest. It is recommended that devices that share a hardware interrupt (e.g. UART0 and UART1) be assigned to the same partition.

11.1.3.3.7.11 Byte-channel configuration

Each partition created by the hypervisor can have virtual resources called byte-channels which provide a virtualized interrupt-driven character-based I/O channel connected to one of several endpoints:

- a physical UART
- a byte-channel in another partition
- a byte-channel multiplexer (mux
- the hypervisor console

Hypervisor GDB stubs also each define a byte-channel for communication. The node defining the configuration of the stub also specifies an endpoint to which the stub communicates.

Guest software interacts with byte-channels using a hypercall interface which allows the sending and receiving of character data. Multiplexing is supported where multiple (up to 32) byte-channels can operate over a single serial line. A de-multiplexing terminal server is required to de-multiplex the channels.

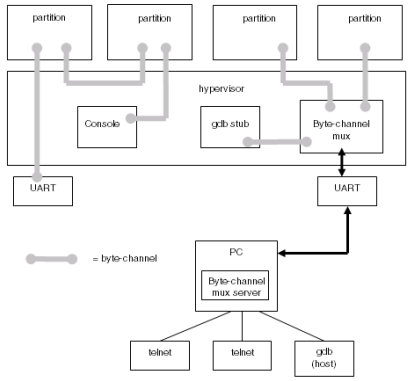


Figure 356. Byte-channel connection example

11.1.3.3.7.11.1 Configuration of Byte-Channels

A byte-channel endpoint is declared by defining a byte-channel endpoint node. This node is a child of the "partition" node. An endpoint property specifies a phandle to another node to which this byte-channel endpoint is attached. If the endpoint is a byte-channel mux, a mux-channel property specifies which channel the byte-channel is to use.

In the guest device tree the byte-channel will have a node under "/hypervisor/handles" which specifies the handle (for use in the hcall API) and interrupt numbers for the byte-channel.

Please refer to the *Embedded Hypervisor Software Reference Manual* [2] for details on how to use the byte-channel hcall API.

The examples below show excerpts from the configuration tree and guest device tree for several byte-channel configurations.

Example 3-5, byte-channel attached to UART

The example below defines a single byte-channel attached to UART1. The *endpoint* property in the partition node associates UART1 with the byte-channel. The guest device tree node contains handles for byte-channel hcalls and interrupt processing.

Hypervisor configuration tree:

```
        hv-config {
                compatible = "hv-config";
                ...
                uart1: uart1 {
                    device = "serial1";
                };
                ...
```

```
        };

        partition1 {
                byte-channel0 {
                    compatible = "byte-channel";
                    endpoint = <&uart1>;
                };
        };
```

Guest device tree:

```
        hypervisor {
            handles {
                byte-channel@6 {
                    compatible = "fsl,hv-byte-channel-handle";
                    reg = <6>;   // handle to byte-channel
                    interrupts = <10 0>; // handle to interrupt
                };
            };
        };
```

Example 3-6, byte-channel attached to byte-channel mux

The example below defines a byte-channel attached to a mux channel 3. The uartmux node associates UART1 with the mux. The byte-channel specifies the mux as the endpoint and a channel number of 3.

Hypervisor configuration tree:

```
        hv-config {
                compatible = "hv-config";
                ...
                uart1: uart1 {
                    device = "serial1";
                };
                ...
        };

        uartmux: uartmux {
                compatible = "byte-channel-mux";
                endpoint = <&uart1>;
        };

        partition1 {
                byte-channel0 {
                    compatible = "byte-channel";
                    endpoint = <&uartmux>;
                    mux-channel = <3>;
                };
        };
```

Guest device tree:

```
        hypervisor {
            handles {
                byte-channel@7 {
```

```
                compatible = "fsl,hv-byte-channel-handle";
                reg = <7>;   // handle to byte-channel
                interrupts = <11 2>;  // handle to interrupt
            };
        };
    };
```

Example 3-7, byte-channel declared for use between 2 partitions

The example below defines two partitions, each with an endpoint connected through the same byte-channel.

Hypervisor configuration tree:

```
    partition1 {
        p1-bc0:byte-channel0 {
            compatible = "byte-channel";
            endpoint = <&p2-bc0>;
        };
    };

    partition2 {
        p2-bc0:byte-channel0 {
            compatible = "byte-channel";
            endpoint = <&p1-bc0>;
        };
    };
```

Guest device tree for part1:

```
    hypervisor {
        handles {
            byte-channel@8 {
                compatible = "fsl,hv-byte-channel-handle";
                reg = <8>;   // handle to byte-channel
                interrupts = <12 2>;
            };
        };
    };
```

Guest device tree for part2:

```
    hypervisor {
        handles {
            byte-channel@8 {
                compatible = "fsl,hv-byte-channel-handle";
                reg = <8>;   // handle to byte-channel
                interrupts = <15 2>;
            };
        };
    };
```

11.1.3.3.7.12 Inter-partition Doorbell Configuration

To define a doorbell endpoint within a partition, a node is created that represents the endpoint. The type of endpoint (send or receive) is specified with the *compatible* property value of "send-doorbell" or "receive-doorbell". A phandle to the global doorbell node is specified with the *global-doorbell* property.

Example 3-8, doorbell with 2 send endpoints (partitions 2 and 3) and 1 receive endpoint (partition 1)

Hypervisor configuration tree:

```
        doorbells {
                dbell0:doorbell0 {
                    compatible = "doorbell";
                };
        };

        partition1 {
                ...
                doorbell0 {
                    compatible = "receive-doorbell";
                    global-doorbell = <&dbell0>;
                    node-update  {
                        prepend-stringlist = “compatible”, “no-mem”;
                    };
                };
                ...
        };
        partition2 {
                ...
                doorbell0 {
                    compatible = "send-doorbell";
                    global-doorbell = <&dbell0>;
                    node-update  {
                        prepend-stringlist = “compatible”, “no-mem”;
                    };
                };
                ...
        };
        partition3 {
                ...
                doorbell0 {
                    compatible = "send-doorbell";
                    global-doorbell = <&dbell0>;
                    node-update  {
                        prepend-stringlist = “compatible”, “no-mem”;
                    };
                };
                ...
        };
```

The doorbells defined in the above example would have the following representation in guest device trees.

Guest device tree for partition1:

```
        handles {
            doorbell@8 {
                compatible = “no-mem”,
                             "fsl,hv-doorbell-receive-handle";
```

```
                interrupts = <12 0>;
        };
};
```

Guest device tree for partition 2:

```
handles {
    doorbell@9 {
        compatible = “no-mem”, "fsl,hv-doorbell-send-handle";
        reg = <9>;   // handle to doorbell

    };
};
```

Guest device tree for partition 3:

```
handles {
    doorbell@8 {
        compatible = “no-mem”, "fsl,hv-doorbell-send-handle";
        reg = <8>;   // handle to doorbell
    };
};
```

11.1.3.3.7.13 Managed Partitions

The hypervisor provides the ability for one partition to manage other partitions. Management involves the capability to:

- Start, stop, restart managed partitions (via hypercall APIs)
- Receive doorbell interrupts from managed partitions for certain events
  - watchdog expiration
  - managed partition state change
    - transition from starting to running
    - transition from stopping to stopped
    - transition from pausing to paused
    - transition from resuming to running
  - restart request
- Send a doorbell interrupt to a managed partition to request that it cleanly shut down

Management ability is granted to the 'manager' partition via a declaration in the manager's partition node. See the reference manual [2] for an overview of partition management and the available partition management hypercalls and interrupts.

To specify the manager/managed relationship between two partitions a partition management node is declared in the partition node of the manager partition. This node contains a partition property which has a value which is a phandle to the managed partition.

Configuration Node Example

The "p1-linux" partition is defined to be the manager of "part2" which is referenced by phandle.

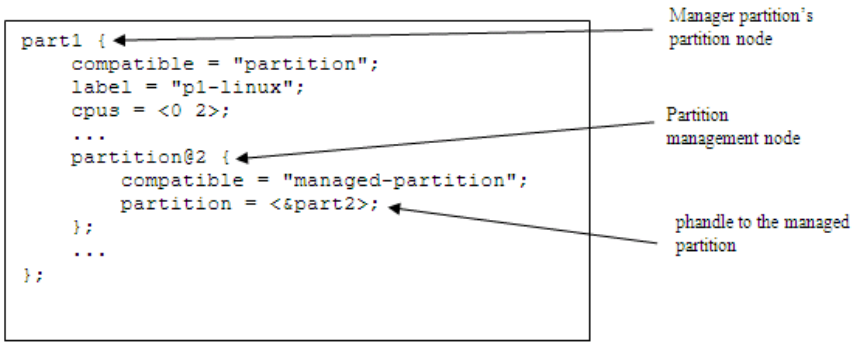

Figure 357. partition node for managing another partition

Guest Device Tree Examples

For the configuration node example in 3-9, the following is what the guest device tree would look like for the manager and managed partition:

Manager partition:

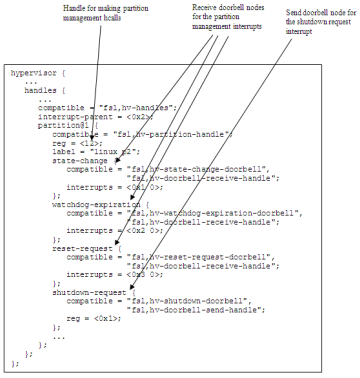

Figure 358. manager partition guest device tree

Managed partition:

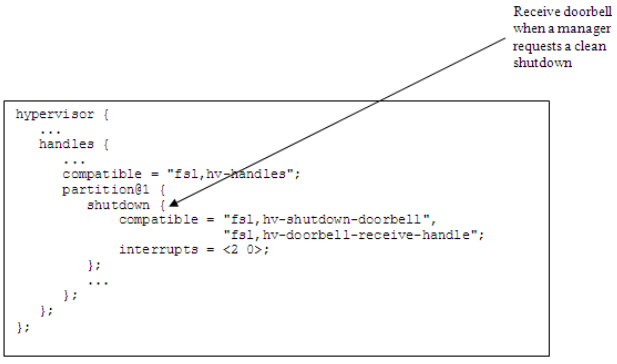

Figure 359. managed partition guest device tree

11.1.3.3.7.14 Guest Aliases

By default all devices assigned to a partition that have an alias in the hardware device tree have the alias copied to the guest device tree. They are copied verbatim, but are updated to correctly reflect the structure of the guest device tree which may be somewhat different than the hardware tree.

In addition, a guest aliases node can be specified under a partition node to add additional aliases to the guest device tree. The name of this node must be *aliases*. The value must be a phandle to a node in the hypervisor configuration tree. The phandle values are resolved to a string value that is the full path to the referenced object in the guest device tree.

Example:

Hypervisor configuration tree:

```
aliases {
    stdout = <&bc2>;
};
```

Guest device tree:

```
aliases {
    ...
    stdout = "/hypervisor/handles/byte-channel2";
};
```

11.1.3.3.7.15 Guest root node properties

The partition node supports a node-update node (see Guest device tree node updates on page 2275) which updates the root node of the guest device tree.

Example:

Hypervisor configuration tree fragment:

```
partition2 {
    ...
    node-update {  // update to the root node
        model = "P4080-Linux";
        chosen {
            foo = "bar";
        };
    };
    ...
};
```

Guest device tree:

```
/ {
    model = "P4080-Linux";
    ...
    chosen {
        foo = "bar";
    };
```

```
        ...
    };
```

11.1.3.3.7.16 Debug stub node

The hypervisor supports debugging guest software using debug stubs within the hypervisor. A host debugger such as GDB can attach to hypervisor debug stubs via a byte-channel. Each virtual CPU being debugged has an instance of a debug stub which performs run control and accesses guest hardware state on behalf of the host debugger.

The hypervisor supports stubs for the GDB and CodeWarrior debuggers.

The hypervisor cannot share the physical CPU's debug resources with the guest operating system. In order to allow debug stubs to use the CPU's debug resources the *guest-debug-disable* property must be specified on the partition node which defines a debug stub.

In order to enable a debug stub a special "debug stub" node must be added to the partition node which specifies the byte-channel and virtual CPU the stub is to debug.

- The compatible string for the node must be "gdb-stub" (for GDB) or "trk-stub" (for CodeWarrior).
- The *endpoint* property specifies a phandle to the character device node which this stub is to use for communication. This value must be a phandle to a hypervisor owned character device (e.g. UART) or a byte-channel mux. In the case of a byte-channel mux the channel must also be specified.
- The *debug-cpus* property specifies which virtual CPUs are managed by this stub instance

See the reference manual [2] for full details.

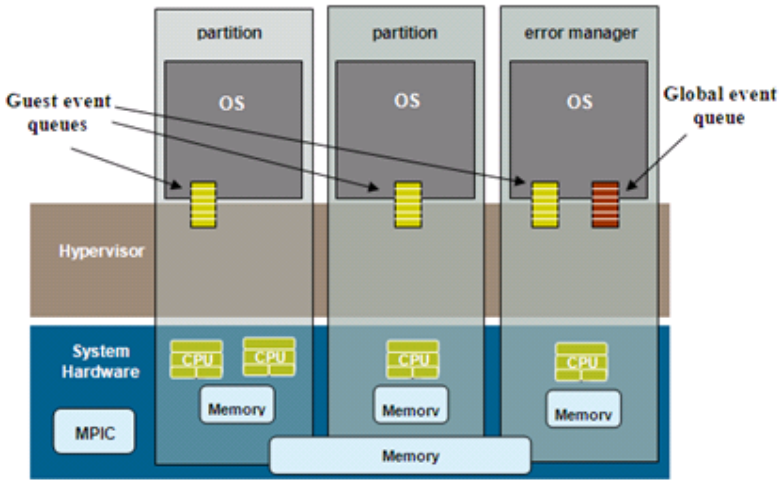
Example

Definition for two gdb stubs debugging a 2 CPU partition—one for debugging virtual cpu 0 (on mux channel 1) and one for debugging virtual cpu 1 (on mux channel 2):

```
    uartmux: uartmux {
        compatible = "byte-channel-mux";
        endpoint = <&uart1>;
    };
    ...
    partition {
        compatible = "partition";
        guest-debug-disable;
        cpus = <0 2>;
        ...
        gdb-stub@0 {
            compatible = "gdb-stub";
            endpoint = <&uartmux>;
            mux-channel = <1>;
            debug-cpus = <0 1>;  //virtual cpu 0
        };
        gdb-stub@1 {
            compatible = "gdb-stub";
            endpoint = <&uartmux>;
            mux-channel = <2>;
            debug-cpus = <1 1>;  // virtual cpu 1
        };
    };
```

11.1.3.3.7.17 Error management

As described in the NXP Embedded Hypervisor Reference manual [2], the hypervisor provides a set of event queues that are used to communicate certain error conditions to partitions.



Guest Event Queue

Each partition has a guest event queue. Partitions will receive notifications of PAMU access violations for a device owned by the partition. Partitions are notified of errors in the guest event queue via a machine check (MCSR[MCP], IVOR1) on virtual CPU #0.

The FH_ERR_GET_INFO hypercall API is used to get the error event information from the queue.

Global Event Queue

There is a single global event queue that is used to communicate certain system errors to a partition designated to be an error manager. The partition designated to be the error manager is specified in the definition of the partition in the hypervisor configuration tree. The notification policy for each system error can be also specified in the hypervisor configuration tree.

The error manager is notified of errors in the global event queue via a critical interrupt (IVOR0). The CPU in the partition to receive the interrupt can be specified in the configuration tree.

The FH_ERR_GET_INFO hypercall API is used to get the error event information from the queue.

11.1.3.3.7.17.1 Global Event Queue Configuration Example

In the hypervisor configuration tree fragment below, *partition1* is designated to be the error manager and the policies for DDR single bit ECC errors are configured.

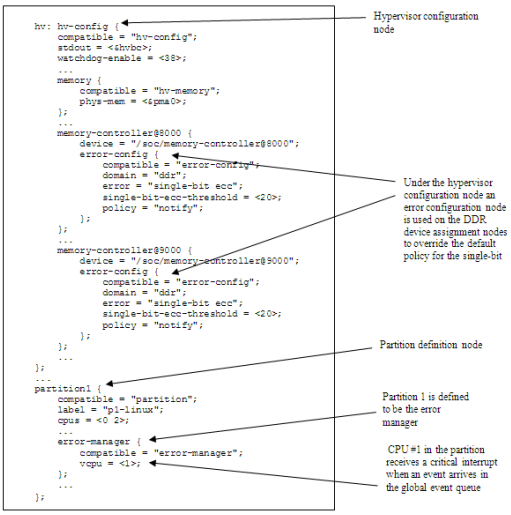


Figure 360. Configuration of Global Event Queue and Error Policies

11.1.3.3.7.17.2 Example - Event Queues in a Guest Device Tree

The global event queue and guest event queue are represented in the guest device tree as shown in the guest device tree fragment shown below :

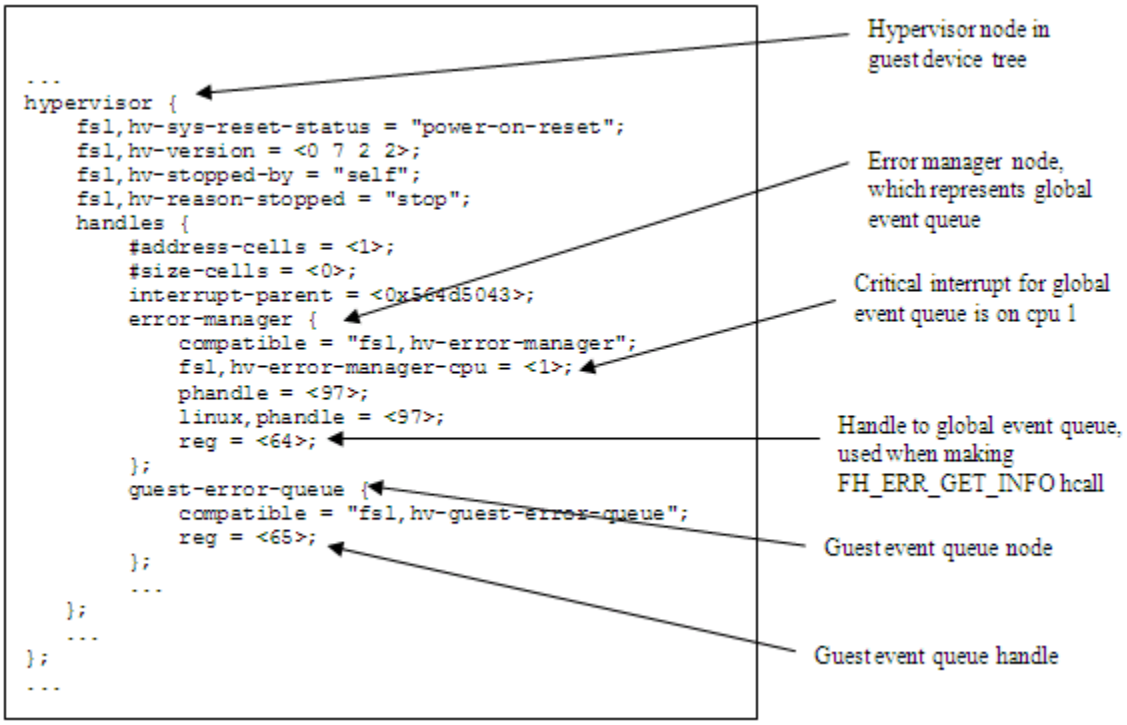

Figure 361. Event Queues in Guest Device Trees

11.1.3.3.7.18 High availability services

The hypervisor provides mechanism to create configurations where partitions can be arranged in an active and standby relationship for high availability. These mechanisms include:

- Notifications on managed partition state changes and watchdog expiration
- Device sharing between active and standby partitions. After an active partition crash, mechanisms exist for the new active partition to claim active ownership of shared devices, include interrupt routing re-configuration and IOMMU updates
- Error manager sharing between active and standby
- System reset if all partitions move into the stopped state (see sysreset-on-partition-stop property).

11.1.3.3.7.18.1 Partition notifications

Partitions can manage receive notification about other partitions using the partition management capabilities of the hypervisor. See Managed Partitions on page 2291 , and the hypervisor reference manual [2] for additional details on partition management features and the partition notifications that may be received.

In order for an active and standby partition to receive notifications they must be configured to manage each other, as shown below.

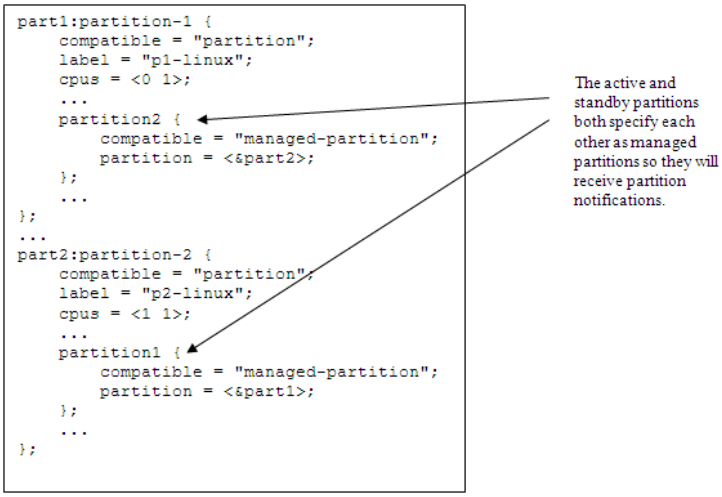

Figure 362. Active/standby partitions and notifications

11.1.3.3.7.18.2 Device Sharing

Devices can be shared between partitions in a failover configuration, whereby one partition has active ownership of a device at a time. Interrupts from the shared device are routed to the active owner. Device errors such PAMU access violations are placed in the error event queue of the active owner of the device.

If the active owner is stopped, another partition configured with access to the device may claim it and become the new active owner. To use this feature, all partitions assigned the shared device must specify the *claimable* property on the device configuration node for the device. At least one partition must have a shared device initially set to be "active". See the hypervisor reference manual [2] for details.

Hypervisor Configuration Tree

The hypervisor configuration tree describes the assignment of devices and which are active and which are standby. In the example below, an SoC-based DMA engine is assigned and shared by two partitions.

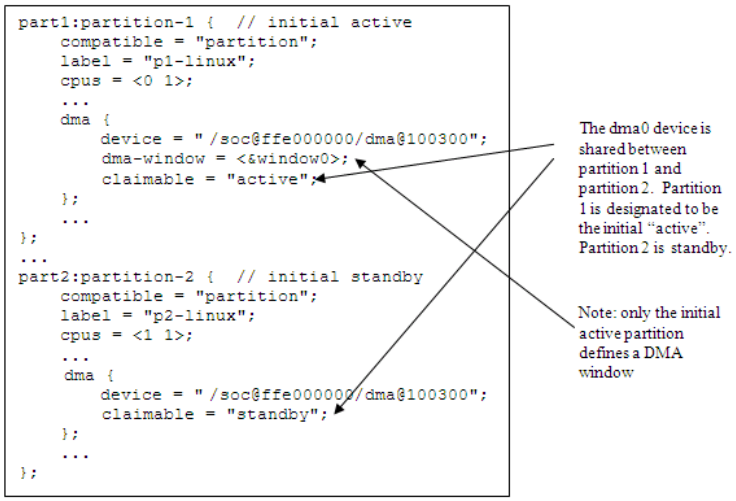

Figure 363. Active/standby Partitions and Device Sharing

Guest Device Trees

The guest device tree passed to the partitions sharing the device reflects the active standby status of a shared device in the node describing the device. The example below shows the guest device trees for a shared DMA engine.

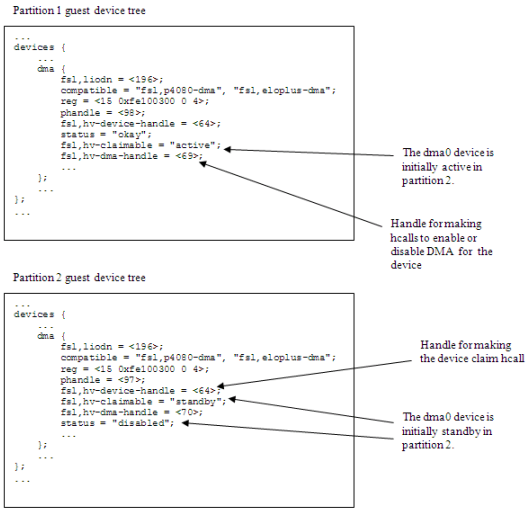

Figure 364. Guest Device Trees and Device Sharing

The partition with the standby device is permitted to map the device's registers, however it must take care to not modify any hardware state as that would potentially interfere with the active partition.

11.1.3.3.7.18.3 Sharing the Error Manager

One partition in the system is designated to be the error manager. This partition receives notification interrupts when there is a system error and has a global event queue containing detailed error information.

The error manager can be shared between active and standby partitions in a manner identical to devices as described in the previous section.

11.1.3.3.7.18.4 Failover Event Flow Example

The example below illustrates a hypothetical event flow for two partitions in an active/standby configuration. The partitions share a device, the SoC-based DMA engine. Partition 1 is the initial active partition with Partition 2 being standby.

Table 577. Failover Event Flow Example

Partition 1	Partition 2
In Partition Definition • Partition 2 is specified as a managed partition • DMA device is assigned with claimable = "active" • Error manager node is specified with claimable = "active" • Partition's watchdog is configured to stop partition on watchdog timeout.	**In Partition Definition** • Partition 2 is specified as a managed partition • DMA device is assigned with claimable = "standby" • Error manager node is specified with claimable = "standby"
Active Partition OS DMA engine driver initializes and manages device normally.	**Standby Partition** OS DMA engine driver sees that device is "standby" and takes care not to touch device registers.
Failover Event Watchdog expires, resulting in partition 1 moving into the “stopped” state. This turns off DMA and disables device interrupts. state change notification interrupt ---------->	**Failover Event** Standby partition receives notification of active partition stopping.
	Failover • Invokes FH_CLAIM_DEVICE to claim active ownership of DMA engine device. • Invokes FH_CLAIM_DEVICE to claim error manager • Invokes interrupt controller APIs to configure and enable interrupts. • Invokes FH_DMA_ENABLE to enable DMA for the DMA engine device • Invokes FH_PARTITION_START to start partition 1
Partition restarts and becomes new standby.	Partition becomes new active.

11.1.3.3.8 Hypervisor Configuration Node

A hypervisor configuration node at the root of the configuration device tree specifies global configuration parameters and the memory and I/O devices assigned to the hypervisor.

- The *compatible* string for the node must be "hv-config"
- A hypervisor memory node (*compatible* = "hv-memory") must be specified which identifies the hypervisor private memory (the PMAs belonging to the hypervisor). The PMA assigned to the hypervisor must provide at least 8MB of memory.
- The *stdout* property specifies the console for the hypervisor. This can refer to a hardware serial port or a byte-channel. This property is only required to override any *stdout* alias specified in the hardware device tree.

See the hypervisor reference manual [2] for additional details.

All I/O devices that the hypervisor manages must be explicitly assigned under the hypervisor in the configuration node.

To have the hypervisor use a UART for a console and/or attached to a byte-channel mux a UART device (compatible = "ns16550") must be assigned to the hypervisor.

NOTE

The following devices must be assigned to the hypervisor for proper operation:

- Interrupt controller (compatible "chrp,open-pic")
- Corenet local access windows (compatible "fsl,corenet-law")
- Corenet coherency fabric (compatible "fsl,corenet-cf")
- Memory controllers (e.g. compatible ""fsl,p4080-memory-controller")
- Platform cache controllers (e.g. compatible "fsl,p4080-l3-cache-controller")
- IOMMU (e.g. compatible "fsl,p4080-pamu")
- Global utilities (compatible "fsl,qoriq-device-config-1.0")
- Specific compatible values may vary depending on the SoC being used.

Example:

```
hv:hypervisor-config {
        compatible = “hv-config”;
        stdout = <&serial0>;

        hv-memory {
            compatible = "hv-memory";
            phys-mem = <&pma0>;
        };

        pamu {
            device = "/soc@fe000000/iommu@20000";
        };

        mpic {
            device = "/soc@fe000000/pic@40000";
        };

        cpc-0 {
            device = "/soc/l3-cache-controller@10000";
        };

        iommu {
            device = "/soc/iommu";
        ;

        cpc-1 {
            device = "/soc/l3-cache-controller@11000";
        };

        corenet-law {
            device = "/soc/corenet-law";
        };

        corenet-cf {
            device = "/soc/corenet-cf";
```

```
                };

                guts {
                    device = "/soc/global-utilities@e0000";
                };

                serial0 {
                    device = "serial0";
                };
        };
```

11.1.3.4 Linux

Two device drivers exist in Linux to support embedded hypervisor functions:

1. A console driver that enables byte-channel based console I/O.
2. A management driver console driver that enables partition management capabilities that can be used by tools like partman.

11.1.3.4.1 Byte-channel Console Driver

The NXP hypervisor byte-channel console driver is part of the **hvc_console** subsystem in Linux.

In order to specify a byte-channel for the Linux console, the *stdout* alias must be set in the configuration device tree to point to a byte-channel endpoint node. Configuring this alias results in the Linux device **/dev/console** being attached to the specified byte-channel.

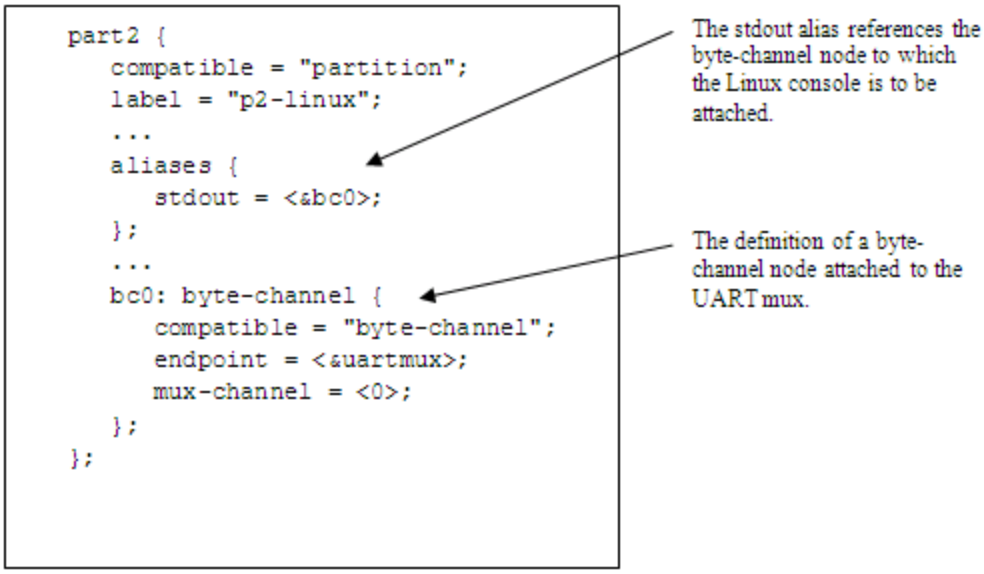

Figure 365. stdout alias for Linux byte-channel console

11.1.3.4.2 Management Driver

The NXP partman utility (described in Partition Management Utility (Linux) on page 2303), is a Linux-based tool for performing partition management tasks. It uses a specialized Linux device driver called **/dev/fsl-hv.**

The management driver provides a character device interface to perform partition management tasks—status, starting, stopping, and image loading for managed partitions. In addition, the partition management receive doorbell interrupts are handled by the driver

The management driver registers itself with the Linux sysfs subsystem. A **/dev/fsl-hv** file must be created with the appropriate major and minor numbers as returned by sysfs. It is recommended that the Linux "udev"or "mdev" facility be used to do this.

Example: To see the major/minor device numbers of fsl-hv:

```
cat /sys/class/misc/fsl-hv/dev
10:63
```

11.1.3.5 Debugging

11.1.3.5.1 Hypervisor Logging

Visibility into hypervisor activity is available through log information written to the hypervisor console. The log level used by the hypervisor is a compile time option and can be set through the hypervisor's Kconfig configuration utility (see Changing the Hypervisor Build Options on page 2308) and the hypervisor shell (see section below).

Log level verbosity can be set with the '*Default console loglevel*' option, with the value zero being no logging and 15 being the most verbose.

In addition, to reduce code size, logging code can be removed from the hypervisor by setting the '*Maximum console loglevel to build for*' option.

11.1.3.5.2 Hypervisor Command Shell

The hypervisor console provides an optional command shell which may be used for debugging. At the **HV**> prompt commands may be entered. See the hypervisor reference manual for details on shell command syntax. The shell also has built-in help to list and describe the supported commands.

Example 5-1

```
HV>
HV> ?
    loglevel (ll) - Control the log level for a specific log type
    crash - Crash the hypervisor.  Used for testing.
    buildconfig (bc) - Display build time configuration
    error_policy - Display error policies
    guestmem (gm) - Dump guest memory
    gtlb - Display guest tlb entries
    resume - Resume a paused partition
    pause - Pause a running partition
    stop - Stop a partition
    restart - Re-start a running partition
    start - Start a stopped partition
    paact - Display PAMU's PAACT table entries
    cdt - Display hypervisor configuration tree
    hdt - Display hardware device tree
    gdt - Guest device tree operation
    reset - Perform a system reset
    info - List partitions and show their status
    version - Print the hypervisor version
    help (?) - Print command usage information
```

```
HV>
```

To display partition info and status:

Example 5-2

```
HV> info
Partition   Name        State         Vcpus
-------------------------------------------
0           /part1      running         3
1           /part2      running         2
```

To display guest TLB entries:

Example 5-3

```
HV> pause 0
HV> gtlb 0 0
TLB 0
                                                          T             SSS UUU I V
Effective                Physical                         S TID   WIMGE XWR XWR P F
------------------------ -------------------------        - ----- ----- --- --- - -

TLB 1
                                                          T             SSS UUU I V
Effective                Physical                         S TID   WIMGE XWR XWR P F
------------------------ -------------------------        - ----- ----- --- --- - -
03  0x40000000 - 0x40000fff 0x020000000 - 0x020000fff    0     0       XWR     1 0
04  0x00100000 - 0x00100fff 0xffe100000 - 0xffe100fff    0     0  I G  XWR     1 0
15  0x20000000 - 0x2fffffff 0x000000000 - 0x00fffffff    0     0   M   XWR     1 0
```

To display the PAMU PAACT table:

Example 5-4

```
HV> paact
        sub                                     sub     stash
        win     base        xlate               win     cache   OMT
liodn   #       addr        addr    size        cnt     id      mode
-------------------------------------------------------------------
196     -       00000000  00000000  1024 MB     0015    000       0
        1       00000000  04000000  0016 MB     -       000       0
        2       01000000  0c000000  0016 MB     -       000       0
        3       02000000  20000000  0064 MB     -       000       0
197     -       04000000  64000000  0064 MB     0000    000       0
```

11.1.3.6 Tools

11.1.3.6.1 Partition Management Utility (Linux)

The hypervisor provides a Linux-based partition management utility called *partman* that works in conjunction with a partition management Linux kernel device driver to provide basic partition management services for a manager partition.

A partition is managed via a handle that the manager partition discovers under the /hypervisor/handles node in its device tree.

A summary of valid combinations of arguments to partman is show below:

Action	Syntax
Show status of a partition	partman [-v] status
Load images into a partition	partman [-v] load -h handle -f file [-a address] [-r]
Start a partition	partman [-v] start -h handle [-f file] [-l] [-e address] [-a address]
Stop a partition	partman [-v] stop -h handle
Listen for doorbells	partman [-v] doorbell -f file
Rings the doorbell of the destination partition	partman [-v] doorbell -h handle
Sets a guest device tree property	partman [-v] setprop -h handle -p dtpath -n propname [-t data [-t data]]
Gets a guest device tree property	partman [-v] getprop -h handle -p dtpath -n propname

Command	Description
`status`	Display the full names and status of all managed partitions. Also shows the handle values to be used for other partman commands.
`load`	Load an image into a partition's memory
`start`	Start a partition. Optionally load a file with -f, or use -l to tell the hypervisor to reload hypervisor-loaded images
`stop`	Stop a partition.
`doorbell`	Listen for doorbells (if -f specified), or ring a doorbell (if -h specified).
`setprop`	Sets a guest device tree property for the specified partition
`getprop`	Gets a guest device tree property for the specified partition.

Option	Description
`-h handle`	For the doorbell command, this specifies the send handle of the doorbell to ring. For all other commands, this specifies the handle of the target partition. Note, the handles used by this command are not the same as the partition numbers used by the hypervisor command shell. Use the status command to list the handles. The partition name call also be used in place of a handle value.

Table continues on the next page...

Table continued from the previous page...

`-f filename`	For the doorbell command, this specifies the program to run when a doorbell is received. This can be any program that can be executed by the shell. partman passes the doorbell handle as a parameter to this script. For all other commands, this specifies the name of the file to load. Three types of images are supported-1) ELF, 2) uImage (u-boot format), 3) binary. If this file is an ELF image, the ELF headers will be parsed and PT_LOAD segments will be extracted and copied to the target partition in the right order. If it is an uncompressed uImage file, the payload of the uImage is extracted and copied to the target partition. Otherwise, the file is treated as a single binary blob.
`-l`	Reload images. Used with the start command to direct the hypervisor to reload hypervisor-loaded images.
`-a address`	Optional guest physical address where the image should go. For ELF images, this parameter defaults to the base physical address in the image. For binary images, the default is 0.
`-e address`	Optional guest physical address of execution entry point. For ELF images, this parameter defaults to the entry point in the image. For binary images, the default is 0.
`-t data`	A string that is that value to write to the specified property using the setprop command. Integer and other binary values are not supported.
`-p dtpath`	Device tree path. A string that specifies the full path to the node for which the property is being accessed.
`-n propname`	Property name. A string that specifies the name of the property which is being accessed.
`-v`	Verbose output. Useful for debugging.
`-q`	Quiet mode. Errors reported via return status only.
`-r`	Specifies that the image is a root filesystem. It is used with the load command to pass the correct size information to the kernel. This parameter is optional.

Example

The examples below show a sequence of loading 2 images into a managed partition, starting the partition, then stopping it.

To see the status of partitions:

```
# partman status
Partition Name                  Handle  Status
----------------------------------------------
p3-linux                        71      stopped
p2-linux                        66      stopped

Byte Channel Name               Handle  RX Int  TX Int
------------------------------------------------------
bc-p3                           85      83      84
bc-p2                           82      80      81
console                         79      77      78

Doorbell Name                   Handle  Type
--------------------------------------------
shutdown                        76      receive
p3-linux/reset-request          74      receive
p3-linux/watchdog-expiration    73      receive
p3-linux/state-change           72      receive
p2-linux/reset-request          69      receive
p2-linux/watchdog-expiration    68      receive
p2-linux/state-change           67      receive
doorbell-in                     65      receive
p3-linux/shutdown               75      send
p2-linux/shutdown               70      send
doorbell-out                    64      send
```

To load a root filesystem image in partition "p2-linux" at guest physical address 0x1300000 in the p2-linux managed partition:

```
# partman load -h p2-linux -f rootfs.ext2.gz -a 0x1300000 -r
```

To load an image in partition "p2-linux" at guest physical 0x0:

```
# partman load -h p2-linux -f vmlinux -a 0x0
```

To start partition "p2-linux" at entry point of guest physical address 0x0:

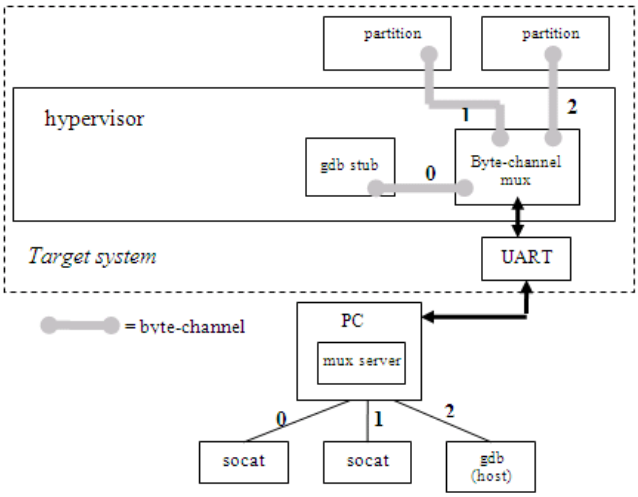
```
# partman start -h p2-linux -e 0x0
```

To stop partition "p2-linux":

```
partman stop -h p2-linux
```

11.1.3.6.2 Mux-server Utility (Linux)

The hypervisor supports multiplexed serial communications via byte-channels. In the configuration device tree each byte-channel that is to be multiplexed specifies a channel number in the definition of the byte-channel end point (see Byte-channel configuration on page 2287). The Linux-based mux_server utility is provided to support multiplexing and demultiplexing services. The mux server runs on a host system and attaches to the target system via a serial or network communications channel. it can be located in the standard Yocto output directory, subdirectory 'hv'.



Syntax: mux_server [-s <baud-rate>] <target> <channel_port> ...

Where:

<**baud-rate**> is the baud rate (default is 115200)

<**target**> is connection to the target board that the mux_server is providing mux/de-mux services to. This would typically be a serial port (e.g. /dev/ttys0) or a host:port in the case of network based connection to the target.

<**channel_port**> is a list of network ports corresponding mux channel numbers, starting with channel 0. So, the first port listed is channel 0, second port is channel 1, etc.

For mux channels that service console output, a variety of tools exist that provide an interactive display of the console data:

- socat (in raw mode)
- putty (in raw mode)

Examples

To attach to a target at /dev/ttys0 and export mux channel 0 on port 8000 and mux channel 1 on port 8001:

```
mux_server /dev/ttys0 8000 8001
```

For this example, to connect to the mux_server with an interactive console on mux channel 0 on host "falcor"

```
socat -,raw,echo=0 tcp:falcor:8000
```

11.1.3.6.3 Switching mux channels without a mux server

The hypervisor and mux_server use a simple channel switch protocol to multiplex the streams of data. ASCII 0x18 (CTRL-x) indicates a channel switch and is followed by a byte specifying the channel number-0x30 indicates channel 0, 0x31 indicates channel 1, etc. See the hypervisor reference manual [2] for a detailed description of the mux protocol.

The channel switch commands allow easy channel switching with only a single console session and no mux server using the CTRL-x character. The character sequence CTRL-x 0 selects channel 0. CTRL-x 1 selects channel 1, and so on.

11.1.3.7 Building and deploying the embedded hypervisor

11.1.3.7.1 Building the Hypervisor with Yocto

The embedded hypervisor software is packaged as part of a NXP SDK which provides the necessary tools needed to build the software. In the context of the *Yocto* package creator, the hypervisor can be built in a standalone manner with the following commands:

```
cd [path-to-yocto-poky-build-folder]
bitbake hypervisor
```

The above commands assume that *Yocto*'s environment had already been configured for a chosen target.

11.1.3.7.2 Changing the Hypervisor Build Options

The hypervisor provides a number of build time parameters that can be changed via the hypervisor's Kconfig utility. These options allow the developer to select only required features which will reduce the hypervisor's code size.

To change the build time configuration options do the following:

```
cd [path-to-yocto-poky-build-folder]
bitbake -c cleansstate hypervisor
bitbake -c menuconfig hypervisor
```

Note: The first bitbake command forces a clean build. This is needed due to how Yocto tracks build dependencies. If it is not provided, the hypervisor won't be rebuilt and thus the new configuration won't be taken into consideration.

A menu will appear that shows the configuration of certain build time parameters. Built in help is provided for these build options. The basic user interface is similar to the Linux kernel's Kconfig tool.

See the screenshot below.

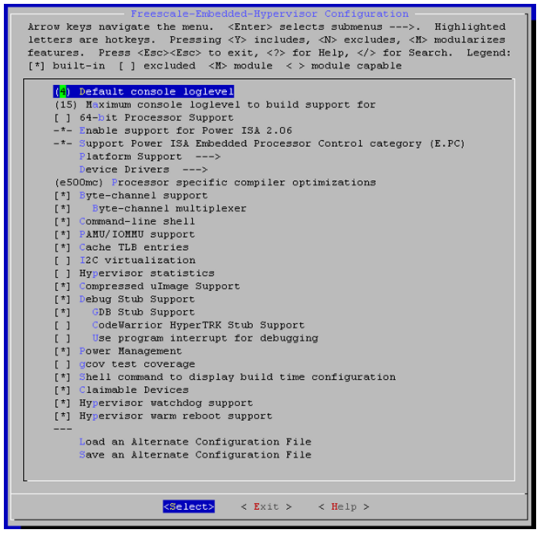


Figure 366.

After making desired build configuration changes, exit and save the configuration.

To build the hypervisor and make Yocto re-deploy the hypervisor image, follow the following steps:

```
cd [path-to-yocto-poky-build-folder]
bitbake hypervisor
```

11.1.3.7.3 Deploying the Hypervisor with U-Boot

The hypervisor must be booted with an ePAPR compliant boot program such as u-boot. In the context of u-boot, five distinct images are required to boot a system with the hypervisor:

- u-boot image (the "boot program")
- hypervisor image (the "client program", typically packaged as a uImage in the context of u-boot)
- hardware device tree (DTB format)
- hypervisor configuration tree (DTB format)
- one or more guest OS images

In the context of u-boot, the hypervisor is the client program to be booted. U-boot passes a pointer to the hardware device tree to the hypervisor as specified in the ePAPR. The **bootargs** property must be set on the /**chosen** node of the hardware device tree to specify the parameter **config-addr** that tells the hypervisor where to find the configuration tree.

Example - Booting the Hypervisor with U-boot

In this example, assume images are at true physical addresses as described below:

hypervisor image: 0xe8700000

hardware device tree: 0xe8800000

hypervisor configuration tree: 0xe8900000

Table 578. booting hypervisor with u-boot

```
=> setenv bootargs config-addr=0xe8900000
=> bootm e8700000 - e8800000
```

The physical addresses of the guest OS images are specified in the partition definition within the configuration tree. See Loading Images on page 2279.

11.1.3.8 Porting an operating system to the NXP Embedded Hypervisor

The required changes that must be made to an operating system in order to have it execute as a guest under the NXP Embedded Hypervisor can be divided into 4 general categories:

1. *Initial state & boot*—the hypervisor provides an boot environment compliant with the ePAPR standard [1]. This defines the initial state of a partition and how secondary CPUs are started. An OS not compliant with the ePAPR may require minimal changes to parse the device tree passed to it.
2. *CPU*—no OS changes should be required for basic CPU operation, however there are some differences between the physical and the virtual CPU that should be considered.
3. *SoC Platform*—the SoC platform consists of all hardware resources outside the e500 family cores. A notable platform-related change involves guest OS use of the interrupt controller.

4. *Additional hypervisor provided resources and services*—in order to take advantage of hypervisor services such as byte-channels, inter-partition doorbells, and partition management, OS modifications are required.

Considerations for each area will be explored in more detail in the sections that follow.

The general philosophy adopted in the hypervisor architecture is to require no OS changes to with respect to the CPU core. That is, the hypervisor uses full virtualization where supervisor- level instructions and registers behave as they would on a native hardware e500mc/e5500.However, OS changes may be required to certain device drivers in order to access hypercall based services offered by the hypervisor.

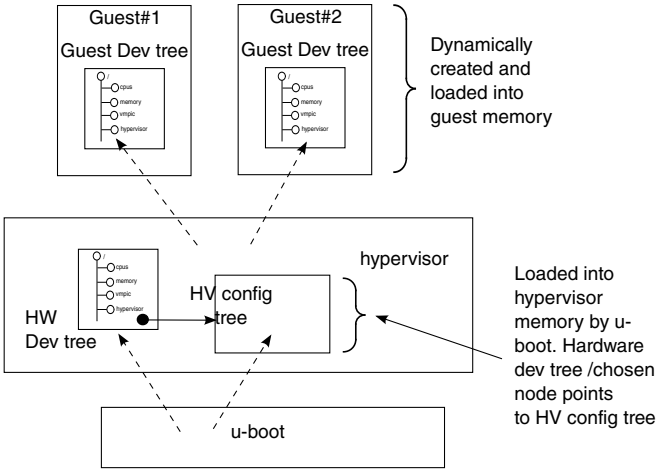
NOTE

Note: One basic assumption is that the operating system has been ported to the native e500mc/e5500 CPU. The hypervisor virtual CPU is identical in most respects to the physical CPU and thus an OS port to the e500mc/e5500 is a foundational step.

11.1.3.8.1 Initial State and Boot

The ePAPR [1] is a standard that specifies the interface between a boot program (e.g. bootloader, firmware, hypervisor) and a client program (e.g. OS, hypervisor). It defines boot-time mechanisms and the state of the platform at boot time.

A key aspect of the ePAPR is the concept of a device tree, which is a data structure that represents the hardware of a system. A device tree is passed to an ePAPR-compliant OS when it is booted. In the context of the NXP Embedded Hypervisor, a "guest device tree" is passed to the partition at boot and describes the subset of hardware resources and virtual resources that have been assigned to the partition.



The guest device tree defines nodes representing:

- CPUs
- Memory
- I/O devices
- Hypervisor specific information including virtual resources such as byte-channels, doorbells, and partition management relationships.

Guest device trees are fully described in the hypervisor reference manual [2].

An OS must be minimally device tree aware. The DTC tool (used to compile device trees from "device tree syntax" (DTS) form to "device tree blob" (DTB) form) provides a C library called libfdt. The libfdt library provides a full range of APIs to parse and manipulate device trees and will make the process of adding device tree awareness to an OS straightforward.

At a minimum an OS must determine the interrupt numbers for each hardware device from the guest device tree passed when the OS is booted. These interrupt numbers are opaque handles used as an argument to the VMPIC services APIs.

If the partition has multiple CPUs in it, the multi-CPU boot mechanisms specified by the ePAPR must be used. The guest device tree and spin table must be used in the ePAPR to release secondary CPUs.

The ePAPR specifies the initial state of the system when control is transferred to an OS.

11.1.3.8.2 CPU Related Changes

When running on the hypervisor, operating systems run in a hypervisor-controlled environment referred to as a partition. The OS view of CPUs and other hardware resources is identical or nearly identical to that of the native hardware, except that the hypervisor controls and manages the privileged resources of the system. This virtualized hardware environment is sometimes referred to as a virtual machine. One aspect of the virtual machine is the CPU. A "virtual CPU" looks nearly identical to the native CPU minus the hypervisor extensions (category Embedded.Hypervisor in the Power ISA 2.06). This means few, if any, changes are required to guest OS software with respect to basic CPU operation. Supervisor level instructions and behave as expected, with a few minor exceptions (see below).

Guest operating systems run in supervisor mode (MSR[PR]=0). This means that guest OS access to hypervisor privileged resources such as the MMU will cause a hypervisor privilege exception. The hypervisor then performs the expected behavior of the instruction or register access for the OS in a process referred to as emulation. Emulation is mostly transparent to the guest and few OS modifications should be required.

However, there are some subtle differences between a virtual CPU and a native CPU running in supervisor mode—mostly in terms of some additional restrictions. These differences are detailed in the NXP Embedded Hypervisor Software Reference Manual [2], and are summarized below. As previously mentioned a first step in porting an OS to run on the hypervisor is to port the OS to the e500mc/e5500.

The list below is a summary of differences between the physical CPU and the hypervisor virtual CPU:

- **Timebase**. The TBU and TBL SPRs are read-only. The hypervisor takes care of timebase synchronization across all CPUs.
- **Processor ID register**. The PIR is read-only to guest software. The hypervisor sets PIR to the vcpu number within the partition.
- **Cache locking**. If an operating system relies on locking cache lines, the behavior of **dcbtls,dcbtstls, dcblc, icbtls**, and **icblc** depends on the **guest cache lock** mode configuration setting in the hypervisor. Guest cache lock mode grants software in the partition the ability to lock the cache.
- **Cache Control Registers**. Certain cache control register bits may not be written. For example, an OS may not turn off caches. See the hypervisor reference manual [2] for complete details.
- **Reservations.** The ability to emulate an atomic operation using **lwarx** and stwcx is based on the conditional behavior of stwcx, the reservation set by lwarx, and the clearing of that reservation if the target location is modified by another processor or mechanism before the stwcx performs its store. In the virtual CPU a reservation is lost for any of the reasons described in the physical CPU specification and additionally any of the following reasons:
  - Invocation of a hypercall
  - Execution of certain supervisor privileged instructions which are emulated (such as TLB operations). See the hypervisor reference manual [2] for further details. This means that locks cannot be held across these emulated instructions.
  - Access to certain supervisor privileged SPRs. See the hypervisor reference manual [2] for further details.
- **Watchdog timer**. The definition of the TCR[WRC] bits is different than a native CPU. The only watchdog reset permitted is a partition reset. For managed partitions, a watchdog timeout results in an interrupt being sent to the manager partition.
- **BUCSR** (branch prediction control). BUCSR is read-only.
- **CDCSR0** (Core Device Control and Status Register 0). CDCSR0 is read-only.

- **MMU**. The number of TLB entries in TLB0 and TLB1 is different than that of a native CPU. Iterating over TLB0 using tlbre is not supported. The tlbilx instruction is present (even though it is part of category Embedded.Hypervisor) and is recommended for performing TLB invalidations.
- **Hypervisor resources**. The features and capabilities of the physical CPU defined by the category Embedded.Hypervisor in the 2.06 Power ISA™ are **not** features of the virtual CPU. These differences include:
  - The MSR[GS] bit is always set and cannot be changed.
  - The GS bit and LPID are not part of the virtual CPU's virtual address
  - Accesses to Embedded.Hypervisor category SPRs such as MSRP, LPIDR, MAS5, MAS8 are boundedly undefined. See the hypervisor reference manual [2] for further details.
  - If 64-bit category is implemented, only ICM field of EPCR register is accessible. For 32 bit guests the register is not accessible.
  - The EGS and ELPID fields in EPLC and EPSC are not writeable
  - For msgsnd, the LPIDTAG field is ignored. The G_DBELL, G_DBELL_CRIT, and G_DBELL_MC message types are not supported.
- **Thread management instructions, SPRs, TMRs.** All the thread management resources are emulated by the hypervisor: reads act as if the core has a single hardware thread (e.g. a dual-threaded e6500 core will be exposed to a guest as two single-threaded e6500 cores) writes will trigger a warning in the Hypervisor console.

Refer to the hypervisor reference manual [2] for complete details.

An operating system developer must evaluate the use of each of the above features and modify the OS to comply with the

11.1.3.8.3 SoC Platform Changes

The system-on-a-chip platform consists of the non-CPU resources such as memory-mapped I/O devices and registers. Operating systems have restricted ability to access the platform.

Most peripherals and I/O devices can be assigned directly to partitions, and thus the OS can use unmodified, native device drivers to access the devices.

However, the following devices are hypervisor-owned and should be only accessed using hypervisor provided services:

- Interrupt controller (see vmpic services)
  - The MPIC timers are not available for guest use
- Global Utilities
  - Power management
  - Clock control
  - Reset control
- Peripheral Access Management Unit (PAMU)
- DDR memory controllers (for error management)

Any guest OS access to the above resources will require modifications to use the hypervisor services provided by hypercalls.

Interrupt Controller Services

A notable platform change required in an OS will be to use the hypervisor interrupt controller services. The hypervisor interrupt controller services use a processing model identical to that of the native MPIC hardware, except that hypercall APIs are used to access manage interrupts. The table below shows the interrupt controller APIs.

Table 579. Interupt Controller Hypercalls

Hypercall	Description
EV_INT_SET_CONFIG	Configures the specified interrupt
EV_INT_GET_CONFIG	Returns the configuration of the specified interrupt
EV_INT_SET_MASK	Sets the mask for the specified interrupt source
EV_INT_GET_MASK	Returns the mask for the specified interrupt source
EV_INT_EOI	Signals the end of processing for the highest-priority interrupt currently in service.
FH_VMPIC_GET_MSIR	Gets the MPIC MSIRx (Shared Message Signaled Interrupt Register) associated with the specified interrupt source

Each interrupt generating device is dynamically assigned an opaque interrupt handle that is set in the device's interrupt specifier in the guest device tree. Interrupt handles are used in the in the API to manage the interrupt source.

The QorIQ supports an improved interface between the MPIC and CPUs called Coreint. With Coreint mode, normal external interrupts (defined as not *critical*, not *machine check,* or not *debug*) are delivered via a new interface between the MPIC and the processor core(s), called CoreInt. The CoreInt interface "pushes" the interrupt vector into the core where it can be read through a special purpose register. This reduces interrupt service latency since the interrupted processor core is no longer required to query the MPIC's IACK register to acknowledge obtain the interrupt vector.

The hypervisor supports an optional mode called *direct EOI* that in some circumstances, where CPUs and devices are dedicated to a partition, allows an EOI with no hcall. See the hypervisor reference manual [2] for additional details.

11.1.3.8.4 Additional hypervisor provided resources and services

The hypervisor provides a number of other optional services that may be used as needed by operating systems. Some services are hyper-call based and thus require OS modifications to create device drivers to use the services.

These services include the following:

- Byte-channels
- Inter-partition doorbell interrupts
- Partition management
- Shared memory

Byte-channels

Byte-channels are an interrupt-driven character-based I/O channel with functionality is similar to a UART. The hypervisor can be configured to multiplex multiple streams of character over a single physical UART. In a system with a limited number of UARTs byte-channels provide a flexible mechanism by which OSes can each get one (or more) character I/O interfaces for use as a console or debugging. The table below shows the interrupt controller APIs.

Table 580. Byte-channel Hypercalls

Hypercall	Description
EV_BYTE_CHANNEL_SEND	Sends data to a byte-channel (up to 16 characters).

Table continues on the next page...

Table 580. Byte-channel Hypercalls (continued)

EV_BYTE_CHANNEL_RECEIVE	Receives bytes of data from a byte-channel (up to 16 characters)
EV_BYTE_CHANNEL_POLL	Returns the status of the byte-channel send and receive buffers

A device driver must be written for an operating system to use the byte-channel service. NXP provides a reference Linux device drivers.

Interpartition Doorbell Interrupts

Interpartition doorbell interrupts provide a mechanism for a sending partition to interrupt one or more destination partitions. Operating system driver code must be developed to use this service. The table below shows the doorbell API.

Table 581. Interpartition Doorbell Hypercalls

Hypercall	Description
EV_PARTITION_SEND_DBELL	Sends a doorbell interrupt to the destination partitions which are associated with the specified doorbell.

The partition that receives the doorbell will have a "receive" doorbell node in its guest device tree containing an interrupt specifier for the doorbell. The doorbell is handled through the normal external handling mechanisms of the OS, but a doorbell specific driver must be created to handle the doorbell.

Partition Management

The hypervisor architecture supports the concept of a manager partition which can use hypervisor provided partition management services. A manager partition has the capability to start, stop, and restart other partitions using hyper calls. For partitions in the stopped state a manager partition can copy data to and from the managed partition, thus enabling the manager to load OS and other images into the managed partition. The table below shows the partition management APIs.

Table 582. Partition Management Hypercalls

Hypercall	Description
FH_PARTITION_START	Boots and starts execution of the specified partition.
FH_PARTITION_STOP	Stops a partition.
FH_PARTITION_RESTART	Requests that the current partition be reinitialized and restarted.
FH_PARTITION_GET_ STATUS	Gets the status of a partition.
FH_PARTITION_MEMCPY	Copies data to/from another partition's memory.
FH_PARTITION_GET_DTPROP	Gets a guest device tree property from the specified partition
FH_PARTITION_SET_DTPROP	Sets a guest device tree property in the specified partition

Shared Memory

The hypervisor provides a configuration mechanism that allows a system architect to define memory that may be shared between partitions. The existence of shared memory is communicated to a guest OS through the guest device tree. Shared memory appears as memory nodes and OS software must be developed to discover and utilize the nodes.

It may be necessary to use the node-update feature of the configuration device tree to update the memory nodes so they will be not be treated as belonging to the available general purpose memory.

Appendix A - Using a gdb stub to Debug a Partition

The hypervisor supports debugging guest operating systems via a debug stub. Host debuggers supported include gdb and CodeWarrior. The debug stub is resident inside the hypervisor and communicates to the host debugger via a byte-channel (which is normally attached directly to a UART, or a byte-channel multiplexer which is attached to a UART).

The example below shows how gdb may be used to attach to a partition with a running guest operating system.

A stub and communications channel must be specified in the partition node definition for each CPU participating in the debug session. See section .

Step 1 - Partition Configuration. Each debug stub requires a debug stub node per virtual CPU to be defined in the configuration device tree. The stub node specifies the communications channel to be used and which virtual CPU number is handled by the stub. The *guest-debug-disable* property must be set on the partition node in order to grant the CPU debug resources to the debug stub. In the example below, partition 1 which has 1 CPU defines one "gdb-stub" node which specifies uart1 as the communications channel.

Table 583. Configuration tree fragments defining debug stub node

```
/* hypervisor configuration node */
hv-config {
    compatible = "hv-config";
    ...
    uart0: uart0 {
        device = "/soc@fe000000/serial@11c500";
    };
    ...
};

uartmux: uartmux {
    compatible = "byte-channel-mux";
    endpoint = <&uart0>;
};

/* partition node for partition 1 */
partition1 {
    compatible = "partition";
    label = “partition 1”;
    guest-debug-disable;
    cpus = <1 1>;
    ...
    gdb-stub@0 {
        compatible = "gdb-stub", "debug-stub";
        endpoint = <&uartmux>;  // byte-channel endpoint
        mux-channel = <1>;
        debug-cpus = <0 1>; //virtual cpu 0
    };
};
```

Step 2 -Attaching with gdb.

After booting the target system, start the host gdb debugger and attach to the configured communications channel. In this example, assume that the target system's UART is connected to /dev/ttys0 of the host system. A hypervisor mux is used and the gdb stub mux is on channel 1.

On the host system start the mux server (mux channel 1 is on port 8001)

```
$ mux_server /dev/ttys0 8000 8001 &
```

Start gdb and attach to port 8001

```
$ powerpc-linux-gnu-gdb

GNU gdb (Sourcery G++ Lite 4.2-171) 6.7.50.20080107-cvs
Copyright (C) 2008 Free Software Foundation, Inc.
License GPLv3+: GNU GPL version 3 or later <http://gnu.org/licenses/gpl.html>
This is free software: you are free to change and redistribute it.
There is NO WARRANTY, to the extent permitted by law.  Type "show copying"
and "show warranty" for details.
This GDB was configured as "--host=i686-rh73-linux-gnu --target=powerpc.
For bug reporting instructions, please see:
<https://support.codesourcery.com/GNUToolchain/>.

(gdb) target remote :8001
```

At this point gdb connects to the hypervisor and a normal gdb debug session can begin.

Selected GDB commands supported by the gdb stub:

- Run control:
  - next
  - step
  - stepi
- Breakpoints
  - To set a software breakpoint: ***break***
  - To set a hardware breakpoint (up to 2 supported): ***hbreak***
  - To set a data breakpoint: ***watch*** **,** ***awatch***
- Reset
  - To reset the partition: **monitor restart**

Freescale KVM/QEMU Release Notes
05/29/2016

Overview
--------
This document describes new features, current limitations, and
```

```
known issues in KVM and QEMU for NXP QorIQ SDK 2.0

New Features
------------

Linux and QEMU versions:
  o  KVM is based on the SDK 2.0 Linux kernel
  o  QEMU is based on QEMU 2.4.0

Limitations Power based Platforms
-----------------------------------------

The following items describe known limitations with this release
of KVM/QEMU for Power based platforms.

  o Memory

       -Because QEMU maps all guest memory (and the mappings are
        cacheable because of Linux limitations), to avoid inconsistent
        TLB mappings guest OSes must not map memory as cache-inhibited (I=1).

  o QEMU
       -the only kernel image type supported are files in uimage format,
        created with the u-boot mkimage tool.

  o virtual CPU features
       -the fixed interval timer is not supported
       -hardware implementation dependent registers (HIDx)
        are not supported
       -L1 and L2 cache control registers are not supported
       -cache locking instructions (dcbtls, dcbtstls, dcblc, icbtls,
        icblc) are not supported
       -the CPU debug resources (debug registers, interrupt) are not
        implemented
       -the CPU performance monitor resources (performance counters
        and interrupt)
       -a hardware machine check that occurs while a virtual machine
        is running will cause QEMU to exit

  o e6500 CPU Features

       -On e6500 CPUs, hardware threads are exposed to virtual machines
        as cores, not threads.   Guest software will see a single
        threaded e6500 virtual CPU.

  o vfio-PCI on e500mc/e5500/e6500

       -Some current limitations in the PCI passthrough implementation are:

          1. It is mandatory that hugetlbfs-allocated memory be used
             when assigning PCI devices to a virtual machine

          2. PCI devices attached to one PCI controller cannot be assigned
             to different virtual machines. The supported isolation granularity
             is that of the PCI controller.

          3. This also means that PCI devices attached to one PCI controller
             cannot be used by the host kernel and a virtual machine at the
             same time. When doing PCI device assignment, all devices attached
             to a PCI controller should be "unbound" from the host.
```

```
          4. Only PCI devices using MSI interrupts are supported -- legacy
             PCI INTx interrupts are not supported.

  o Linux Kernel Build Limitations

       -It is required that the in-kernel MPIC configuration
        option (CONFIG_KVM_MPIC, "KVM in-kernel MPIC emulation") be enabled
        when building the Linux kernel to use vfio-pci or vhost support

Limitations ARM based Platforms
---------------------------------------

The following items describe known limitations with this release
of KVM/QEMU for ARM based platforms.

  o VFIO-PCI is not supported
  o PMU counters are not supported in the guest
```

11.2.2 KVM/QEMU Release Notes

Freescale KVM/QEMU Release Notes

06/23/2016

Overview

This document describes new features, current limitations, and

known issues in KVM and QEMU for NXP QorIQ LS1012A release.

New Features

Linux and QEMU versions:

o KVM is based on the LS1012A release Linux kernel

o QEMU is based on QEMU 2.4.0

Only basic functionality is supported: basic guest boot without I/O.

Limitations

The following items describe known limitations with this release of KVM/QEMU:

o VFIO-PCI is not supported

o 64K page size in the host kernel is not supported.

Privacy Terms of Use Terms of Sale Feedback

11.2.3 KVM/QEMU Release Notes

This document describes current limitations in the release of KVM and QEMU for NXP SoCs. Copyright (C) 2013-2016 Freescale Semiconductor, Inc.

Freescale KVM/QEMU Release Notes 19/12/2016

Overview

This document describes new features, current limitations, and known issues in KVM and QEMU for NXP QorIQ releases.

New Features

Linux and QEMU versions:

- KVM is based on the current release Linux kernel
- QEMU is based on QEMU 2.6.0

Limitations

The following items describe known limitations with this release of KVM/QEMU for ARM based platforms.

- VFIO-PCI is not supported
- PMU counters are not supported in the guest

1.  OVERVIEW

    1.1 Introduction

        Virtualization enables multiple operating systems to run on a system,
        each in their own isolated virtual machine.  Hypervisors create and
        manage virtual machines, one part of which is a virtual CPU (or vcpu).
        A vcpu emulates a physical CPU and the behavior of instructions,
        registers, and exceptions on the vcpu is nearly identical to
        the physical CPU being emulated.

        This document defines a virtual implementation of a CPU based
        on Freescale's implementation of Book III E of the Power ISA.

        In this document, the vcpu architecture is defined in terms of
        differences between the vcpu and the following physical
        CPUs which an implementation may emulate:
           -e500mc
           -e5500
           -e6500

        The differences between the vcpu and the cpu being emulated
        should be understood by operating systems developers.

    1.3 Definitions

        1.3.1 Virtual CPU (vcpu) and Emulated CPU

              A 'virtual CPU' (or vcpu) is the CPU as seen by
              software running in a virtual machine.  The vcpu
              emulates or behaves similar to some physical CPU--
              the 'emulated CPU'.

        1.3.2 Guest Operating System

              A 'guest operating system' (or 'guest') is an operating
              system running in a virtual machine created by a hypervisor.

        1.3.3 Boundedly Undefined

              The definition of the term 'boundedly undefined' used in this
              specification is identical to the Power ISA:

                  The results of executing a given instruction are said to be
                  boundedly undefined if they could have been achieved by
                  executing an arbitrary finite sequence of instructions
                  (none of which yields boundedly undefined results) in the
                  state the processor was in before executing the given
                  instruction. Boundedly undefined results for a given
                  instruction may vary between implementations, and between
                  different executions on the same implementation.

        1.3.4 Volatile

              The definition of the term 'volatile' used in this
              specification is identical to the Power ISA:

                  Bits in a register or array (e.g., TLB) are considered
                  volatile if they may change even if not explicitly
                  modified by software.

    1.4 Revision History

        Version     Date      Change
        -------------------------------------------------
        1.2        10/26/2011  updated references, msgsnd/msgclr,
                               cache control registers
        1.3        1/5/2012    Added e6500 CPU definitions
        1.4        5/2/2012    Added definitions for EPCR and MMUCFG
        1.5        6/25/2012   Category table updates for categories
                               that were missing
        1.6        5/28/2013   Added missing references to e6500,
                               updated references links, minor
                               clarifications
        1.7        5/16/2016   Drop e500v2 support

2. IMPLEMENTED CATEGORIES

   Table 2-1 below identifies the categories of the Power Architecture
   and EREF implemented by vcpu implementations for e500mc, e5500,
   and e6500.
```

```
   X indicates category is supported in vcpu
   - indicates category is not supported in vcpu
     (Note: any categories not listed are not supported in vcpu)

                              Table 2-1
-----------------------------------------------------------------
                                          Virtual CPU
Feature/Category                  Abrv.   e500mc   e5500  e6500

-----------------------------------------------------------------
[1] Little-Endian mappings are supported for data but not instructions.

The ePAPR 1.1 [3] specification defines "power-isa-*" properties on
CPU nodes that specify which Power Architecture categories are
implemented.

    Property: power-isa-*
    Usage: optional
    Value: <empty>
    Description:
       If the power-isa-version property exists, then for each
       category from the Categories section of Book I of the Power
       ISA version indicated, the existence of a property named
       power-isa-[CAT], where [CAT] is the abbreviated category
       name with all uppercase letters converted to lowercase,
       indicates that the category is supported by the implementation.

       For example, if the power-isa-version property exists and
       its value is "2.06" and the power-isa-e.hv property exists,
```

```
            then the implementation supports [Category:Embedded.Hypervisor]
            as defined in Power ISA Version 2.06.

    A hypervisor should advertise implemented CPU categories on
    CPU nodes.

    An operating system should examine these properties
    to determine categories implemented by a virtual CPU.

3.  REGISTERS

    This section describes differences between registers in a virtual CPU
    compared to the CPU being emulated.

    3.1 Version Registers

        The Processor Version Register (PVR) and System Version Register (SVR)
        return the values of the CPU being emulated.

        Note: a guest should take care regarding what assumptions are made
        based on PVR as there are differences between the virtual
        CPU and the CPU being emulated as described in this specfication.

    3.2 Machine State Register (MSR)

        The machine state register (MSR) in the vcpu has differences in
        the following MSR fields as defined in Table 2-1.

             Bits    Name              Description
            ---------------------------------------------------------------
              35      GS       Guest state. MSR[GS] is read-only and is
                               always '1'. (See Note1)

              37     UCLE      User-mode cache lock enable.  Is writeable
                               and behaves as per the architecture if the
                               vcpu implements category "Embedded.Cache Locking".
                               Otherwise is '0' and is read-only.

              54      DE       Debug interrupt enable.  Is writeable and
                               and behaves as per the architecture if
                               DBCR0[EDM]=0.  If DBCR0[EDM]=1, then MSR[DE]=0
                               and is read-only. (see Note2)

            ---------------------------------------------------------------

          Notes
          -----

              Note1 - The MSR[GS] bit is defined only when the CPU being
                      emulated implements Category: Embedded.Hypervisor.

              Note2 - If the vcpu implements category "Embedded.Enhanced Debug",
                      when MSR[DE]=1, the registers SPRG9, DSRR0, and DSRR1
                      are volatile.

    3.3  CPU Index and Processor ID Register (PIR)

          The Processor ID Register is read-only.

          At virtual machine initialization, each vcpu in the virtual machine is
```

```
        assigned a unique index (within the partition) that can be used to
        distinguish the CPU from other CPUs in the partition.

        This CPU index value can be read by using the mfspr instruction to
        read the processor ID register (PIR).

        The CPU index is used in several instances:

           -The index enables software to detect whether a CPU is the boot
            CPU in an SMP configuration. The CPU index of the boot CPU is
            set by software in the device tree header (see ePAPR [3]).

           -If the vcpu implements Category: Embedded.Processor Control, the
            index is used as a parameter to the msgsnd and msgclr instructions
            to specify the targeted CPU for intra-partition signaling.

           -Interrupt source configuration in the VMPIC interrupt controller
            allows specifying the index of the CPU that is configured to
            receive the interrupt.

         Each CPU node is described in the device tree. The reg property
         for each CPU node has a value that matches the CPU index.

   3.4  External PID Load Context (EPLC) and External PID Store Context
        (EPSC) Registers

        A virtual CPU may implement [Category: Embedded.External PID]
        of the Power ISA.  EPLC and EPSC specify the context for external
        PID loads and stores as defined by the Power ISA.

        The EGS and ELPID fields in EPLC and EPSC specify the hypervisor
        context and are not accessible by supervisor level software on
        the vcpu.  Values written to the EGS and ELPID fields are
        ignored.

   3.5  Timebase (TLB and TBU)

        The TBU and TBL are read-only.

   3.6  L1 and L2 Cache Control Registers

       The behavior of the L1 and L2 cache control registers is dependent
       on whether the virtual CPU implements category "Embedded.Cache Locking".

       All L1 and L2 cache control registers and L2 error registers
       can be read regardless of whether category "Embedded.Cache Locking"
       is implemented.

       When category "Embedded.Cache Locking" is _not_ implemented:
          -The L1CSR0[CUL] and L1CSR1[ICUL] fields can be written.  For all
           other fields writes have no effect.

       When category "Embedded.Cache Locking" is implemented:
          -Writes to the flash lock clearing bits are supported--
           L1CSR0[CLFR], L1CSR1[ICLFR], L2CSR0[L2FLC]
          -Writes to the L1CSR0 sticky status bits are supported--
           L1CSR0[CUL], L1CSR0[CSLC], L1CSR0[CLO]
          -Writes to the L1CSR1 sticky status bits are supported--
           L1CSR1[ICUL], L1CSR1[ICSLC], L1CSR1[ICLO]
          -Writes to the L2CSR0 sticky status bits are supported--
```

```
          L2SCR0[L2LO]
         -Support for L1CSR0[DCBZ32] is implementation defined
         -For all other fields writes have no effect.

3.7  Branch Unit Control and Status Register (BUCSR)

     If the cpu being emulated implements BUCSR, the BUCSR fields are
     identical to those of the cpu being emulated. The BUCSR can be read,
     but is not writeable on the vcpu. Writes are NOPs and do not affect
     architectural state.

3.8  Core Device Control and Status Register 0 (CDCSR0)

     If the emulated CPU implements CDCSR0, the CDCSR0 fields are
     identical to those of the CPU being emulated. CDCSR0 can be read but
     is not writeable on the vcpu. Writes are a NOP and result in no
     architectural state changes.

3.9  Debug Registers

     The DBCR0 register in the vcpu is always readable.

     If DBCR0[EDM]=1, then the implementation has not granted debug
     resources to the vcpu.  In this case all accesses to debug
     registers (except reading DBCR0) are boundedly undefined.

     If DBCR0[EDM]=0, then the debug registers implemented by
     the CPU being emulated are supported excepted as noted below.

     Writes to the debug registers and fields in Table
     2-7 are not supported and ignored.  Reads return 0x0.

                        Table 2-7
           ------------------------------------------------
           Debug        Register fields
           Register     not supported
           ------------------------------------------------
            DBCR0       IDM - internal debug mode
                        FT - freeze timers
                        IRPT - interrupt taken
                        RET - return debug event
                        RST - reset

            DBSRWR      all fields

            DDAM        all fields

            DEVENT      all fields
           ------------------------------------------------

    When MSR[DE]=1, the registers SPRG9, DSRR0, and DSRR1 are
    volatile.

3.10 Embedded Processor Control Register (EPCR)

     EPCR is implented if category 64-bit is supported.  All bits
     in EPCR are reserved except for ICM.

         Bits    Name              Description
        ---------------------------------------------------------------
```

```
              38      ICM      Controls the computation mode for all interrupts.
                               At interrupt time, EPCR[ICM] is copied into
                               MSR[CM].

                                   0 Interrupts will execute in 32-bit mode.
                                   1 Interrupts will execute in 64-bit mode.
           -------------------------------------------------------------

    3.11 Hardware Threads

        e6500 CPUs have multiple hardware threads, but threads may
        not be exposed in a virtual machine.  No assumption should
        be made about the number of threads available based mechanisms
        such as PIR.  A e6500 vcpu may only have one thread.

        The Thread Management Configuration Register 0 (TMCFG0) should
        be used to determine the number of threads in a virtual CPU.

4.  INSTRUCTIONS

    4.1 Cache Locking Instructions

        The behavior of cache locking instructions (dcbtls, dcbtstls,
        dcblc, icbtls, icblc) is dependent on whether the virtual CPU
        implements category "Embedded.Cache Locking".  When category
        "Embedded.Cache Locking" is implemented cache locking instructions
        behave as per the architecture.   If cache locking is not implemented,
        executing cache-locking instructions is effectively a nop-- the
        operation is ignored.

    4.3 System Call instruction

        The sc instruction behaves as per the architecture except for the
        following: in user mode MSR[PR=1], sc with LEV == 1 results in a
        program exception with ESR[PPR] set (privileged instruction exception).

    4.4 Wait for Interrupt Instruction

        The 'wait' instruction stops synchronous processor activity
        including the fetching of instructions until an asynchronous
        interrupt occurs.  It is possible that a spurious 'wakeup'
        could occur where instruction fetching is resumed even
        when no vcpu interrupt or no loss of reservation occurred.

    4.5 Reservations

        The ability to emulate an atomic operation using "load with
        reservation" instructions and "store conditional" instructions
        is based on the conditional behavior of "store conditional",
        the reservation set by "load with reservation", and the clearing
        of that reservation if the target location is modified by another
        processor or mechanism before the "store condtitional" performs
        its store.

        The following considerations should be understood regarding potential
        reservation loss. With the vcpu, a reservation may be broken for
        the following reasons:

           -The Power ISA lists reasons where reservation may be lost
```

```
            -An asynchronous interrupt in the physical CPU may cause a loss
             of a reservation, including interrupts not visible to or caused
             by guest software.

            -A reservation may be broken if software executes a privileged
             instruction or utilizes a privileged facility. Privileged
             instructions and facilities are defined by the Power ISA.

    4.5 tlbilx

        The tlbilx instruction is supported on e500mc, e5500, and e6500
        virtual CPU implementations even though category E.HV is not
        supported.

    4.6 msgsnd/msgclr

        The msgsnd and msgclr instructions are defined by cateogry
        "Embedded.Processor Control" and are supported if the category
        is implemented on the cpu being emulated.

        The vcpu does not implement category "Embedded.Hypervisor".
        An attempt to use the E.HV features of msgsnd/msgclr is
        boundedly undefined.

5.  MMU

    5.1 Overview

        Software running on an vcpu implementation should not make
        assumptions about the configuration or geometry of the vcpu's
        MMU based on the PIR register.  Instead, software should determine
        MMU configuration from the MMUCFG and TLBnCFG registers.  The vcpu's
        MMU configuration may be different from the CPU being emulated.

    5.2 TLBnCFG NENTRY and ASSOC

        The Power ISA [1] specifies how TLBnCFG[NENTRY] and TLBnCFG[ASSOC]
        should be interpreted.  This definition is summarized in
        the table below:

          NENTRY  ASSOC      Meaning
          ----------------------------------------------------------------------
           0       0         no TLB present

           0       1         TLB geometry is completely implementation-defined.
                             MAS0[ESEL] is ignored

           0       >1        TLB geometry and number of entries is
                             implementation defined, but has known
                             associativity.
                             For tlbre and tlbwe, a set of TLB entries is
                             selected by an implementation dependent function
                             of MAS8[TGS][TLPID], MAS1[TS][TID][TSIZE], and
                             MAS2[EPN]. MAS0[ESEL] is used to select among
                             entries in this set, except on tlbwe if
                             MAS0[HES]=1.

           n > 0   n or 0    TLB is fully associative
          ----------------------------------------------------------------------
```

```
    5.3 IPROT=0

        A TLB entry with IPROT=0 may be evicted at any time.

    5.4 MMUCFG

        The LPIDSIZE field (bits 36-39) can be used by software to
        detect whether category E.HV is present.  A value of 0 indicates
        that E.HV functionality is not present.

6.  EXCEPTIONS

    6.1 Debug Interrupts

        The vcpu does not support delayed/deferred debug interrupts:

            -If MSR[DE]=0 and a debug condition occurs in the
             vcpu, no bit is set in DBSR.

            -Writes to DBSRWR have no effect.

            -Imprecise debug events (DBSR[IDE]) and unconditional debug
             events (DBSR[UDE]) are not supported.

            -If a debug event happens with MSR[DE] = 1, and the software
             running on the vcpu fails to clear DBSR before re-enabling
             MSR[DE] another debug interrupt will not occur.

7.  HYPERVISOR SPECIFIC CONSIDERATIONS

    7.1 Cacheable and Cache-inhibited Mappings on KVM

        As part of virtual machine initialization and setup, QEMU (the virtual
        machine manager) also creates mappings to a guest address regions.
        A guest must have I=1 for RAM mappings and I=0 for other mappings
        in order to avoid creating an architecture-violating alias with QEMU's
        mapping.
```

11.2.5 KVM for Power Architecture Users Guide and Reference

11.2.5.1 Introduction to KVM and QEMU

11.2.5.1.1 Overview

This document is a guide and tutorial to building and using KVM (Kernel-based Virtual Machine) on NXP QorIQ SoCs.

Virtualization provides an environment that enables running multiple operating systems on a single computer system. Virtualization uses hardware and software technologies together to enable this by providing an abstraction layer between system hardware and the OS. The isolated environment in which OSes run is known as a *virtual machine* (or VM). The abstraction layer that manages all this is referred to as a *hypervisor or virtual machine manager*. The hypervisor layer operates at a privilege level higher than that of the operating systems, thus enabling it to enforce system security, ensure that virtual machines cannot interfere with each other, and transparently provide other services such as I/O sharing to the VM.

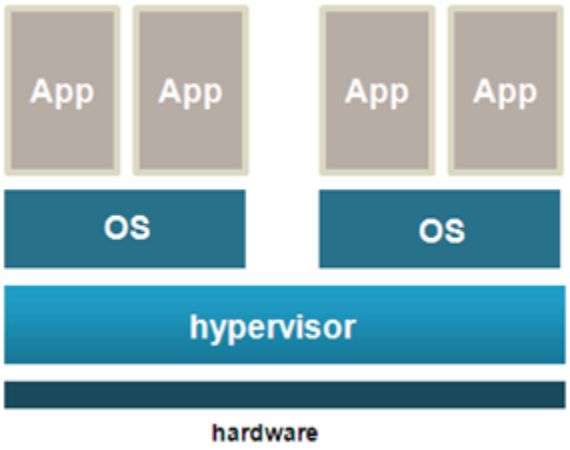

Figure 367.

KVM is a Linux kernel driver that together with QEMU, an open source machine emulator, provides an open source virtualization platfiorm based on Linux. KVM and QEMU together act as a virtual machine manager that can boot and run operating systems in virtual machines. See Figure below.

In this document the term *host* kernel refers to the underlying instance of Linux with the KVM driver that acts as the hypervisor. The term *guest* refers to the operating system, such as Linux, that runs in a virtual machine. A virtual machine will be referred to as a "VM".

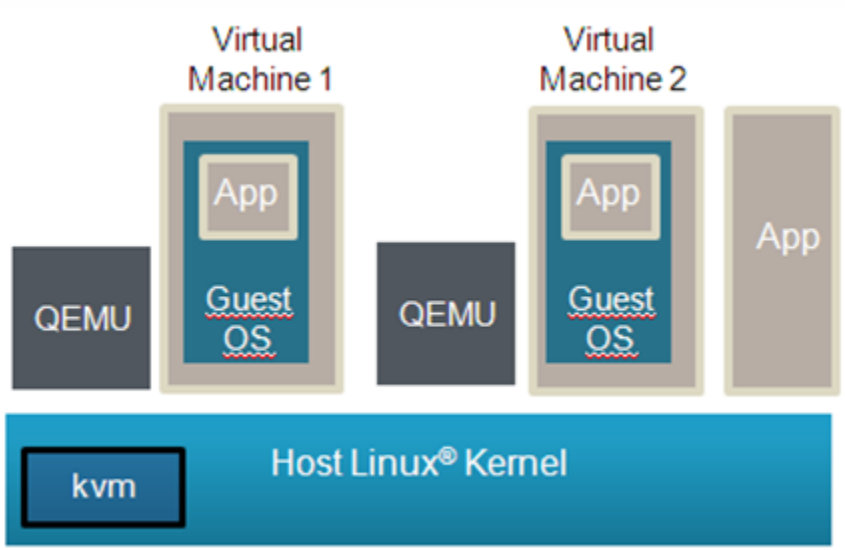

Figure 368.

NXP QorIQ SoCs based on the PowerPC e500mc, e5500 and e6500 CPUs are supported.

11.2.5.1.2 Organization of this Document

This document is organized as follows:

- Introduction to KVM and QEMU on page 2328 provides an introduction to KVM/QEMU, including overview information and references.
- Building QEMU and KVM on page 2334 provides information on how to build QEMU and the Linux kernel with KVM.

- Using QEMU and KVM on page 2338 describes how to use KVM/QEMU, including how to invoke QEMU to start virtual machines and how to set up virtual I/O and passthrough I/O devices.
- Virtual machine reference on page 2347 provides a reference for virtual machines-- details about initial VM state, virtual CPUs, and virtual I/O devices. This information is relevant when porting an OS or device driver to a KVM-based virtual machine.
- Debugging virtual machines on page 2355 describes facilities available for debugging software running in a virtual machine.
- Using KVM/QEMU with libvirt on page 2345 describes how to use the libvirt toolkit to manage KVM/QEMU virtual machines.
- KVM/QEMU How-to's on page 2357 provides a set of examples for common tasks.

11.2.5.1.3 Virtual Machine Overview

A guest OS running in a KVM/QEMU virtual machine "sees" a hardware environment similar to running on a physical board. The guest sees CPUs, memory, and a number of I/O devices. Some aspects of this environment are virtualized (emulated in software by KVM/QEMU) but this virtualization is mostly transparent to the guest, and changes to the guest are typically not required to run in a virtual machine.

The number of virtual machines that can be run simultaneously is only limited by the amount of available resources (like any other application on Linux).

There is limited support for passthrough of physical I/O devices to virtual machines. PCI and USB devices can be directly assigned to virtual machines, making the device a private resource of the virtual machine.

NXP's KVM/QEMU implements an e500-based virtual machine containing the following resources:

- One or more e500 virtual CPUs
- Memory
- Virtual PCI bus (used for virtual devices such as block and network devices)
- Virtual UART
- Virtual MPIC interrupt controller
- Virtual Global Utilities (used for guest OS initiated reset)

11.2.5.1.4 Introduction to KVM and QEMU

QEMU (pronounced KYOO-em-yoo) is a software-based machine emulator that emulates a variety of CPUs and hardware systems. KVM is a Linux kernel device driver that provides virtual CPU services to QEMU. The two software components work together as a virtual machine manager.

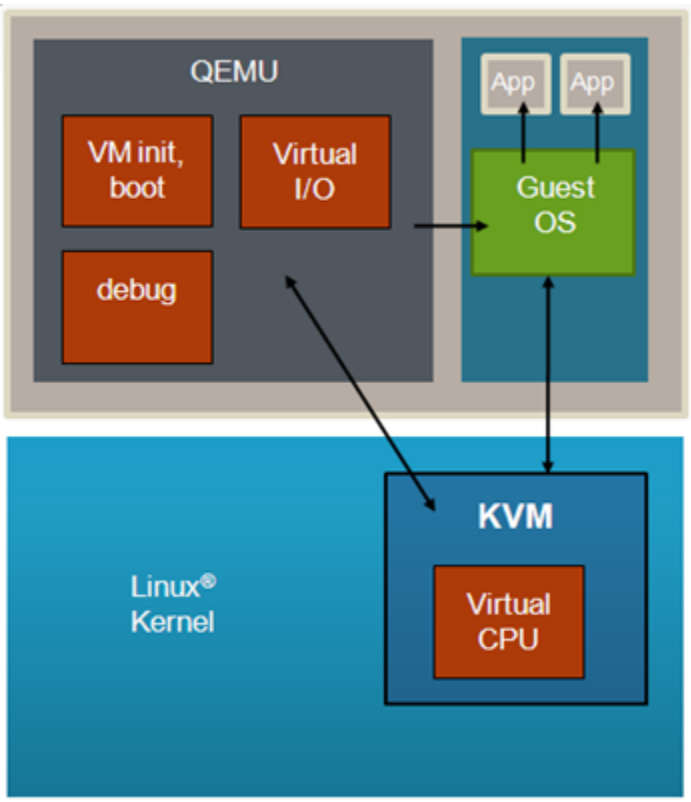

Figure 369.

QEMU is a Linux user-space application that runs on the host Linux instance and is used to start and manage a virtual machine. QEMU provides the following:

- A command line interface that provides extensive customization and configuration of a virtual machine when it is started-- e.g. type of VM, which images to load, and how virtual devices are configured
- Loading of all images needed by the guest-- e.g kernel images, root filesystem, guest device tree
- Setting the initial state of the VM and booting the guest
- Virtual I/O services, such as virtual network interfaces and virtual disks
- Debug services-which provide the capability to debug a guest OS using GDB (similar to a virtual JTAG)

KVM is a device driver in the Linux kernel whose key role in the VM architecture is to provide virtual CPU services. These services involve two aspects:

1. First, KVM provides an API set that QEMU uses to set and get the state of virtual CPUs and run them. For example, QEMU sets the initial values of the CPU's registers before starting the VM.
2. Second, after KVM starts a guest OS, certain operations (such as privileged instructions) performed by the OS cause an exception (or exit) into the host Linux kernel that must be handled and processed by KVM. This handling of traps is referred to as "emulation". These traps are transparent to the guest. For example if a guest executes a **tlbwe** instruction to update a TLB, which is a privileged resource, this results in a trap to KVM which transparently manages the physical TLB on behalf of the guest.

The KVM API is documented in the Linux kernel-- Documentation/virtual/kvm/api.txt.

KVM/QEMU supports virtual I/O which allows sharing of physical I/O devices by multiple VMs. Virtual network and block I/O are supported. See For More Information on page 2333 for references that provide additional information on virtio.

11.2.5.1.5 Device Tree Overview

A device tree is a data structure defined by the ePAPR that describes hardware resources such as CPUs, memory, and I/O devices. An ePAPR-compliant OS is passed a device tree which it reads to determine what hardware resources are available.

The host Linux kernel is booted first, typically by u-boot (an open source bootloader). U-boot passes the kernel a **hardware** device tree that lists and describes all system hardware resources available to the host kernel (CPUs/cores, memory, interrupt controller and I/O).

Similarly, when a guest OS is booted in a KVM/QEMU virtual machine, QEMU passes it a **guest** device tree that describes all the hardware resources in the VM. See Figure below.

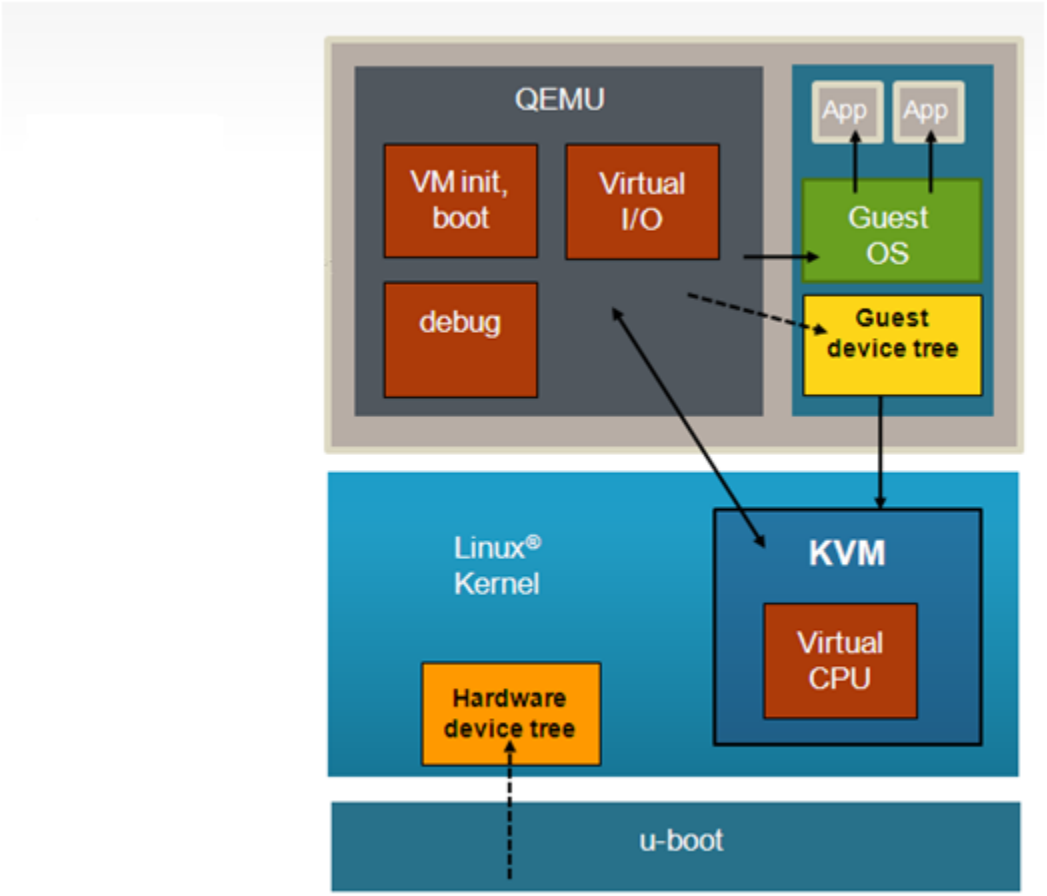

Figure 370.

The guest device tree is generated by QEMU and is used to define the resources a virtual machine will see. The guest device tree defines CPUs, memory, and I/O devices. QEMU places the guest device tree in the virtual machine's memory prior to starting the virtual machine.

11.2.5.1.6 ePAPR

The ePAPR (Embedded Power Architecture Platform Requirements) [2] specification defines platform standards for embedded Power Architecture systems. The ePAPR standard focuses on how a *boot program* (such as boot firmware, or a hypervisor) starts a *client program* (such as an operating system). The ePAPR is oriented to the requirements of embedded systems.

Standards specified in the ePAPR include the following:

- Devices trees, which describe the physical resources in a system. The standard includes:

- The syntax of device tree files (DTS syntax)
- The physical structure of compiled device trees (DTB format)
- Device tree semantics, such as requirements and conventions for the names of nodes and properties
- A description of how hardware busses and interrupts are represented.
- Specific definitions or bindings for the representation of standard hardware resources
- Initial state of a machine when a client program is started including the state of registers and initial memory mappings

- How a boot CPU starts secondary CPUs or threads.

11.2.5.2 Building QEMU and KVM

11.2.5.2.1 Overview

Linux with KVM enabled and QEMU can be built as part of the standard build process used to build the NXP SDK using Yocto.

They can also be built in a standalone manner outside of Yocto.

The build instructions in the sections that follow assume a working understanding of how to use Yocto to build the NXP SDK. Please refer to the Yocto documentation in the SDK.

11.2.5.2.2 Building Linux with KVM

11.2.5.2.2.1 Overview

KVM is a component in the Linux kernel. KVM is not enabled in the default kernel configuration in the NXP SDK and KVM features must be enabled using the kernel's menuconfig configuration utility prior to building the kernel.

In the sections that follow configuration options are described for both the host and guest Linux kernel. The host and guest kernels can be built separately, but it is possible to build a single Linux kernel image that can be used for both the host and the guest.

The kernel configuration options described below would be the same if building the kernel standalone (outside of Yocto).

The following sections provide high level build information:

- Running menuconfig with Yocto - describes how to configure the kernel under Yocto
- Quick Start - Recommended Configuration Options - in a single step shows all the recommended configuration options to enable to build a kernel with virtual I/O enabled with the same kernel image serving as both host and guest.

The following sections provide more detailed information on each KVM-related configuration option for host and guest:

- Host Kernel: Enabling KVM - describes the configuration options to enable KVM in the host kernel.
- Host Kernel: Enabling Virtual Networking - describes how to enable bridging and tun/tap in the host kernel which enables virtual networking.
- Host Kernel: Enabling vfio-pci - describes how to pass through PCI devices to VMs
- Guest Kernel: Enabling Network and Block Virtual I/O -- describes how to enable virtual I/O in the guest kernel.

11.2.5.2.2.2 Running menuconfig with Yocto

The prerequisite and starting point for building the Linux kernel with KVM enabled is performing a standard kernel build with Yocto.

```
$ bitbake virtual/kernel
```

To change the kernel configuration options use the Linux standard menuconfig utility. To invoke menuconfig under Yocto do the following from the Yocto build environment:

```
$ bitbake -c menuconfig virtual/kernel
```

Note: Depending on what build steps may have been done previously, it may be necessary to invoke the command 'bitbake -c clean virtual/kernel' prior to running the menuconfig command.

The result will be an xterm that appears that displays the menuconfig screen:

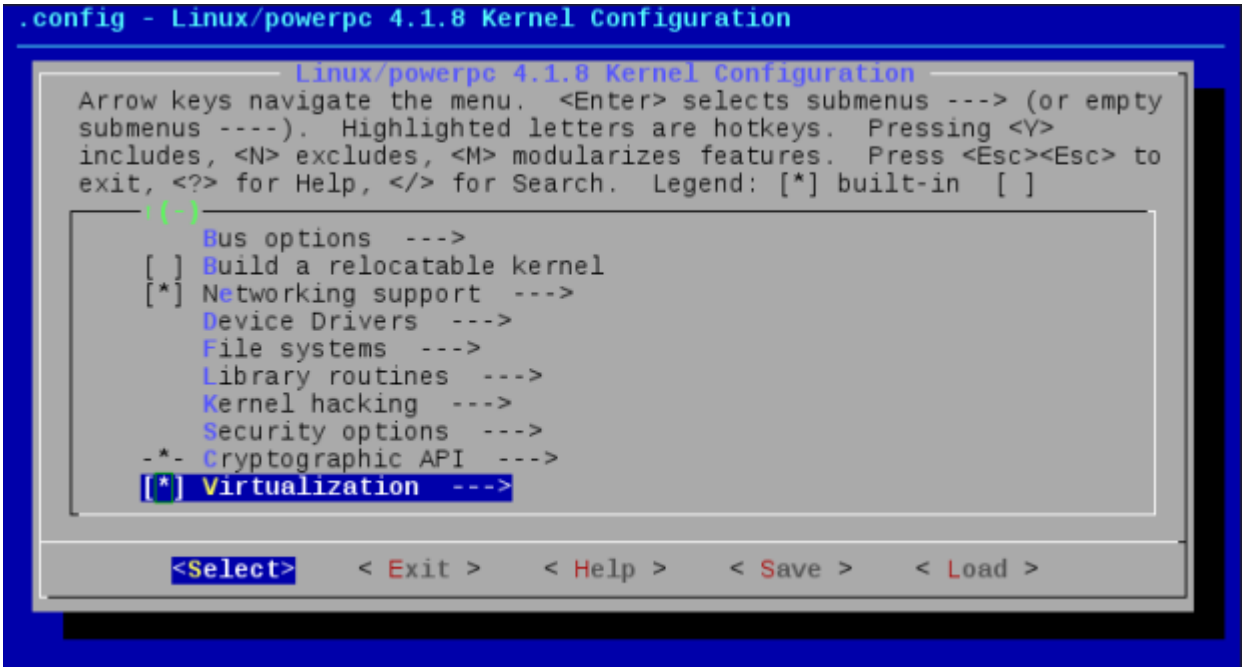

Figure 371.

11.2.5.2.2.3 Quick Start - Recommended Configuration Options

The steps below show all the recommended configuration options to enable to build a kernel with virtual I/O enabled with the same kernel image serving as both host and guest. The sections that follow explain these options in further detail.

1. From the main menuconfig window enable virtualization:

```
[*] Virtualization
```

2. In the virtualization menu enable the following options:

   For e500mc-based systems:

```
[*] KVM support for PowerPC E500MC/E5500/E6500 processors
```

   For all systems:

```
[*] KVM in-kernel MPIC emulation
<*> Host kernel accelerator for virtio net (EXPERIMENTAL)
```

3. Enable network bridging

```
Networking support  --->
    Networking options  --->
        <*> 802.1d Ethernet Bridging
```

4. Enable virtio PCI

```
Device Drivers  --->
    Virtio drivers  --->
        <*> PCI driver for virtio devices (EXPERIMENTAL)
```

5. Enable virtio for block devices

```
Device Drivers  --->
    [*] Block devices  --->
        <*>   Virtio block driver
```

6. Enable virtio for network devices

```
Device Drivers  --->
    [*] Network device support  --->
        <*>   Universal TUN/TAP device driver support
        <*>   Virtio network driver
```

11.2.5.2.2.4 Host Kernel: Enabling KVM

This section describes the core, basic options needed to enable KVM in the host kernel. KVM is enabled in the host kernel under the virtualization menu of the main kernel menuconfig window.

```
[*] Virtualization
```

Core KVM support is enabled as follows:

For e500mc-based (and e5500/e6500 systems) systems:

```
[*] KVM support for PowerPC E500MC/E5500/E6500 processors
```

For all systems enable MPIC emulation

```
 [*] KVM in-kernel MPIC emulation
```

11.2.5.2.2.5 Host Kernel: Enabling Virtual Networking

Virtual network interfaces on page 2342 describes how virtual networking can be used to give each VMs a virtual network interface which share physical network interfaces in Linux.

To get the best available performance enable the Linux kernel-based vhost network acceleration:

```
Virtualization  --->
         <*> Host kernel accelerator for virtio net (EXPERIMENTAL)
```

One common approach to configuring virtual networking is for QEMU to use a tun/tap interface bridged to a physical network interface. To do this, Ethernet bridging and the kernel's tun/tap features must be enabled in the host kernel:

```
Networking support  --->
          Networking options  --->
                    <*> 802.1d Ethernet Bridging
Device Drivers  --->
          [*] Network device support  --->
                    <*>   Universal TUN/TAP device driver support
```

11.2.5.2.2.6 Host Kernel: Enabling vfio-pci

Vfio-pci is a framework that allows PCI devices to be safely passed through to user space applications, and this framework can be used to assign PCI devices to KVM/QEMU virtual machines.

Host Kernel Config -- e500mc/e5500/e6500 based Processors

Processors based on the e500mc/e5500/e6500 all have an IOMMU (PAMU) which is used to provide isolation so that PCI devices assigned to virtual machines are restricted to accessing only a virtual machine's memory.

To enable vfio-pci on e500mc/e5500/e6500:

```
Device Drivers  --->
        <*> VFIO Non-Privileged userspace driver framework  --->
                <*> VFIO support for PCI devices
```

11.2.5.2.2.7 Guest Kernel: Enabling Network and Block Virtual I/O

Virtio is a framework for doing virtual I/O using QEMU/KVM. A virtual machine sees a virtual PCI bus with a special "virtio" virtual network and/or virtual block device on it. Guest software must have virtio drivers to use the devices.

Below the kernel configuration options are shown to enable virtio in the Linux kernel to support networking I/O and block (disk) I/O.

```
Device Drivers
          Virtio drivers  --->
                  <*>   PCI driver for virtio devices
Device Drivers  --->
          [*] Network device support  --->
                    <*>   Virtio network driver
Device Drivers  --->
          [*] Block devices  --->
                    <*>   Virtio block driver
```

11.2.5.2.3 Building QEMU

QEMU is a standard package in the QorIQ SDK and will be built for the following Yocto build configurations:

- fsl-image-virt
- fsl-image-full

To add QEMU to another Yocto build configuration, edit the conf/local.conf file and add the IMAGE_INSTALL_append variable:

```
IMAGE_INSTALL_append = " qemu"
```

After a Yocto build is complete, the target root filesystem will contain the following QEMU components that are required for using KVM/QEMU:

```
/usr/bin/qemu-system-ppc                # QEMU executable (e500mc, e5500 32 bit builds)
/usr/bin/qemu-system-ppc64              # QEMU executable (e5500, e6500 builds)
```

QEMU can be built as an individual component in the Yocto environment as well, it's package name is "qemu".

To clean and rebuild QEMU from the Yocto build environment:

```
$ bitbake -c clean qemu
$ bitbake qemu
```

11.2.5.2.4 Creating a host Linux root filesystem

11.2.5.2.4.1 Overview

Creating a Linux root filesystem is out of the scope of this document. Please reference the NXP QorIQ DPAA SDK for more information on how to create root filesystems with Yocto. This section describes the software components needed on a root filesystem to use KVM/QEMU.

The host root filesystem is the filesystem booted by the host kernel. The host rootfs is distinct from a guest root filesystem which may be needed by certain guest such as Linux.

A host root filesystem capable of running Linux as a guest needs the following components:

- Guest Linux kernel image
- QEMU executable
- Guest root filesystem
- Dynamic libraries needed by QEMU (libfdt, libz, glib2.0). These libraries are standard components in a Yocto-created rootfs.

Example host root filesystem layout with the required components to boot a Linux guest (excluding shared libraries):

```
/root/uImage                                # guest Linux kernel
/root/rootfs.ext2.gz                        # guest rootfs
/usr/bin/qemu-system-ppc                    # QEMU
```

11.2.5.2.4.2 Adding Images to a Root Filesystem with Yocto

If using Yocto, as described in Building QEMU on page 2337, the root filesystem produced by the build process will contain QEMU and the example guest device trees provided by the SDK.

A feature is also available with Yocto and the SDK to add arbitrary additional images to the root filesystem. This is done using the merge-files component in the fsl-image-core and fsl-image-full build image types in Yocto.

Any files and directories copied to the "merge" directory (see path below) will be copied to the root filesystem created by Yocto:

```
fsl-qoriq-sdk/meta-fsl-ppc/recipes-extended/merge-files/merge-files/merge
```

After populating the merge directory with the desired files, clean and rebuild the rootfs. See example below for the fsl-image-core image type:

```
$ bitbake -c install -f merge-files
$ bitbake merge-files
$ bitbake fsl-image-core
```

See the how-to article Quick-start Steps to Build and Deploy KVM Using Yocto on page 2357 for a more detailed example.

11.2.5.3 Using QEMU and KVM

11.2.5.3.1 Overview of Using QEMU

QEMU is used to start virtual machines and is built and included in the rootfs created by Yocto. The QEMU application is named **qemu-system-ppc** for e500mc builds and **qemu-system-ppc64** for e5500/e6500 builds.

In addition to the QEMU executable itself, the following is a list of the minimum components that must be available on the target system to launch a virtual machine using QEMU:

- The host Linux kernel on the target must be built with virtualization support for KVM enabled as described in Building Linux with KVM on page 2334.
- A guest OS kernel image (e.g. uImage for Linux)
- A guest root filesystem (If needed by the guest OS. For example, a Linux guest requires a rootfs.)
- Recommended: A working network interface (to interface to the guest's console and the QEMU monitor)

See the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2359 for an example of how to boot a virtual machine with a rootfs created by Yocto.

The QEMU Emulator User Documentation [1] (see References on page 2333) contains complete documentation for all QEMU command line arguments. The Table below summarizes some of the flags and arguments for basic operation.

Table 584.

Argument	Descriptions
-enable-kvm	Specifies that the Linux KVM should be used for the virtual machine's CPUs
-nographic	Disables graphical output-console will be on emulated serial port.
-M machine	Specifies the type of virtual machine. One value is supported: • ppce500
-smp *cpu_count*	Specifies the number of CPUs for the virtual machine. The number of virtual CPUs allowed is the same as the value of the CONFIG_NR_CPUS config option in the host Linux kernel. To see this value issue the following command from Linux on the target board: `zcat /proc/config.gz | grep NR_CPUS`
-kernel *file*	Specifies the guest OS image. The image must be in uimage format, created with the u-boot mkimage tool. See How to Create a uImage Format Program Image on page 2367.
-initrd *file*	Specifies a root filesystem image
-append *cmdline*	Use *cmdline* as the guest OS kernel command line (passed in the bootargs property of the /chosen node in the guest device tree)
-serial *dev*	Redirects the virtual serial port to the host device *dev*. QEMU supports many possible host devices. Please refer to the QEMU User Documentation [1] (see References on page 2333) for complete details. Note: if using a tcp device with the **server** option QEMU will wait for a connection to the device before continuing unless the **nowait** option is used.

Table continues on the next page...

Table 584. (continued)

Argument	Descriptions
-m megs	Specifies the size of the VM's RAM in megabytes. This option is ignored if using direct mapped memory. See Virtual Machine Memory on page 2341 for further details on options for allocating memory.
-mem-path *path*	Specifies the path to a file from which to allocate memory for the virtual machine. This option should be used to allocate memory from hugetlbfs. See Virtual Machine Memory on page 2341 for further details on options for allocating memory.
-monitor *dev*	Redirects the QEMU monitor to the host device *dev*. QEMU supports many possible host devices. Please refer to the QEMU User Documentation [1] (see References on page 2333) for complete details. Note: if using a tcp device with the **server** option QEMU will wait for a connection to the device before continuing unless the **nowait** option is used.
-S	Do not start CPU at startup (you must type 'c' in the monitor). This can be useful if debugging.
-gdb dev	Wait for gdb connection on device dev
-drive *[args]*	Used to create a virtual disk in a virtual machine. See Virtual block devices on page 2342 for additional information.
-netdev *[args]* -device virtio-net-pci *[args]*	The -netdev and -device virtio-net-pci arguments specify the network backend and front end for creating virtual network devices in virtual machines. See Virtual network interfaces on page 2342 for additional information.
-device usb-ehci *[args]* -device usb-host *[args]*	Assigns the specified host USB device to the virtual machine. The **-device usb-ehci** argument specifies that a PCI-based EHCI USB controller should be added to the PCI bus. The **-device usb-host** identifies the specific USB device being passed through. See Passthrough of USB Devices on page 2343 for additional information.
-device vfio-pci *[args]*	Used to assign host PCI devices to virtual machines. See Passthrough of PCI Devices on page 2343 for additional information.

Table continues on the next page...

Table 584. (continued)

Argument	Descriptions
-watchdog-action *action*	The *action* value specifies the policy for when a CPU watchdog final timeout occurs. Valid values are: • **reset** // the default action, specifies that the VM should be rebooted • **poweroff** // exits QEMU • **pause** // pauses the VM • **debug** // prints a message a continues execution • **none** // no action, continues execution The **shutdown** action is not supported. See section VCPU Watchdog on page 2350.

Below is an example command line a user would run from the host Linux to start an e500mc virtual machine booting a Linux guest:

```
qemu-system-ppc -enable-kvm -nographic -m 256 -M ppce500 -kernel uImage -initrd rootfs.ext2.gz -
append "root=/dev/ram rw console=ttyS0,115200" -serial tcp::4444,server
```

11.2.5.3.2 Virtual Machine Memory

QEMU allocates and loads images into a VM's memory prior to starting the VM. The amount of memory needed for a virtual machine will be dependent on the workload to be run in the VM. There are two ways to allocate memory:

1. Allocation via hugetlbfs

   Hugetlbfs is a Linux mechanism that allows applications to allocate memory backed large physically contiguous regions of memory. QEMU can take advantage of hugetlbfs for allocation of memory for virtual machines, which can provide a significant performance improvement over malloc allocated memory. Hugetlbfs allocated memory provides the flexibility of memory that can be allocated and freed with performance comparable to direct mapped memory.

   See the document Linux HugeTLBFS in the SDK documentation which provides the technical background and detailed information on how to enable and configure hugetlbfs. The Book E implementation in Linux supports 4MB, 16MB, 64MB, 256MB, and 1GB sized huge pages. (Note: 1G huge pages are not supported on 32-bit processors).

   The **-mem-path** argument to QEMU specifies the path to the hugetlbfs mount point where the huge pages should be allocated from.

   The **-m** argument to QEMU specifies the amount of memory to allocate to the virtual machine. There are no constraints on the size passed to this argument other than that the amount of memory must fit within the constraints of the system and be enough for the workload in the VM.

   The base guest physical address of the memory node will be 0x0.

   See the how-to article Quick-start Steps to Run KVM Using Hugetlbfs on page 2359 for an example of how to use hugetlbfs.

   Note: If directly assigning a dma-capable I/O device to a virtual machine, hugetlbfs allocated memory cannot be used. In this case direct mapped memory must be used.

2. Allocation via malloc

   The default for QEMU is to allocate guest memory by the standard malloc facility available to user space applications in Linux. The amount of memory is specified with the -m command line argument. Malloc'ed memory has the flexibility of being allocated and freed by QEMU as needed. However, malloc'ed memory is backed by 4KB physical pages that are

not contiguous and emulation is required by KVM to present a contiguous guest physical memory region to the VM. This approach is discouraged since the emulation can result in a substantial performance penalty for certain workloads.

The base guest physical address of the memory node will be 0x0.

The guest device tree generated by QEMU will contain a memory node that specifies the total amount of memory.

NOTE

A virtual machine's memory is part of the address space of the QEMU process. This means that the amount of memory allocated to a VM is limited by the standard limits that exist for Linux processes. A 32-bit host kernel has a 3GiB virtual address space used for stack, text, and other data, and this limits the amount of memory that can be allocated to a VM.

11.2.5.3.3 Virtual network interfaces

QEMU provides a number of options for creating virtual network interfaces in virtual machines. Virtual network interfaces are specified using the QEMU command line and guest software discovers them by probing the virtual PCI bus.

There are two aspects of virtual network interfaces with QEMU:

1. The network “front-end”, which is the network card as seen by the guest on the PCI bus. This is specified with the **-device** QEMU argument. The argument to specify a virtio network front end would look like: **-device virtio-net-pci**
2. The network "backend", which connects the network card to some network. Network backend options include user mode networking, a host TAP interface, sockets, or virtual distributed Ethernet. The network backend is specified using the **-netdev** command line argument of QEMU. Note: It is possible to connect two virtual machines using virtual network interfaces.

For example, to use a virtio NIC card with a TAP interface back-end the QEMU command line argument would look like:

```
-netdev tap,id=tap0,script=/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -device
virtio-net-pci,netdev=tap0
```

The script “/root/qemu-ifup” is a script that QEMU invokes and passes the TAP interface name as an argument. For example, the script could add the TAP interface to an Ethernet bridge. The script "/root/qemu-ifdown" is called with the TAP interface as parameter, except this time it is called when the virtual machine stops. Following the same example, this script should remove the TAP interface from the Ethernet bridge.

See the QEMU Users Manual [1] (see References on page 2333) for detailed information about command line options and the types of network interfaces and backends. For best performance, the virtio front-end is recommended.

For additional information about QEMU networking see the references in For More Information on page 2333.

For a detailed example, see the how-to article How to Use Virtual Network Interfaces Using Virtio on page 2360 .

11.2.5.3.4 Virtual block devices

There are a number of approaches to provide a virtual disk to a KVM/QEMU virtual machine. A guest disk image can be a single raw file on the host filesystem, a file in a virtual disk format such as qcow2 and vdi, or a block device on the host Linux system. The virtual disk is assigned on the QEMU command line. In the example below, the file **my_guest_disk** is a disk image and is assigned to the VM when QEMU is launched:

```
-drive file=my_guest_disk,cache=none,if=virtio
```

Refer to the QEMU Users manual [1] (see References on page 2333) for details on the types of virtual disk images that may be created and the related arguments to QEMU.

For a detailed example, see the how to article How to Use Virtual Disks Using Virtio on page 2362.

11.2.5.3.5 Passthrough of USB Devices

USB devices can be assigned to virtual machines. When the device is assigned to the virtual machine it becomes the private resource of the VM and cannot be used by the host Linux. The virtual machine sees a EHCI USB controller on its PCI bus. The EHCI controller supports USB 2.0 devices.

There are two approaches for passing through a USB devices-- 1) by specifying the USB vendor ID and product ID of the device, or 2) by specifying the USB bus and port number.

In the examples below, the **-device usb-ehci** argument specifies that a PCI-based EHCI USB controller should be added to the PCI bus. The **-device usb-host** identifies the specific USB device being passed through.

To assign the device by vendor and product ID, first identify the device using the lsusb command. For example:

```
# lsusb
Bus 002 Device 002: ID 13fe:1e23 Kingston Technology Company Inc.
Bus 001 Device 001: ID 1d6b:0002 Linux Foundation 2.0 root hub
Bus 002 Device 001: ID 1d6b:0002 Linux Foundation 2.0 root hub
```

To assign the Kingston USB disk, specify the following -device arguments to QEMU:

```
-device usb-ehci,id=ehci
-device usb-host,bus=ehci.0,vendorid=0x13fe,productid=0x1e23
```

To assign the device by USB bus and host number, use the lsusb command:

```
# lsusb -t
/:  Bus 02.Port 1: Dev 1, Class=root_hub, Driver=fsl-ehci/1p, 480M
    |__ Port 1: Dev 2, If 0, Class=Mass Storage, Driver=usbfs, 480M
/:  Bus 01.Port 1: Dev 1, Class=root_hub, Driver=fsl-ehci/1p, 480M
```

In this example, the storage device can be seen on bus 2, port 1. The info usbhost in the QEMU monitor can also be used to display the host USB bus and port numbers for all USB devices.

To assign the Kingston USB disk by bus and port number, specify the following -device arguments to QEMU:

```
-device usb-ehci,id=ehci
-device usb-host,bus=ehci.0,hostbus=2,hostport=1
```

11.2.5.3.6 Passthrough of PCI Devices

PCI devices can be assigned or passed through to virtual machines. This makes the assigned device the private resource of the VM, and the VM can directly access the device's registers.

NOTE

Some current limitations in the PCI passthrough implementation are:

1. PCI devices attached to one PCI controller cannot be assigned to different virtual machines. The supported isolation granularity is that of the PCI controller.
2. This also means that PCI devices attached to one PCI controller cannot be used by the host kernel and a virtual machine at the same time. When doing PCI device assignment, all devices attached to a PCI controller should be "unbound" from the host.
3. A PCI device that is passed through to a virtual machine cannot be bound back to the host-- a system reboot is required to do this

See the article Host Kernel: Enabling vfio-pci on page 2336 for information on how to build the host and guest Linux kernels to enable vfio-pci.

All VMs have a virtual PCI bus where they discover virtual devices such as network interfaces, virtual disks, etc. Assigned PCI devices appear as another device on the VM's PCI bus.

One requirement for assigning PCI devices is to use hugetlbfs allocated memory for the virtual machine. This provides the virtual machine with larger physically contiguous regions. See the article Virtual Machine Memory on page 2341 for additional information

Follow the steps below to assign a PCI device to a virtual machine.

Step 1. **Identify the device**. To assign a PCI device, first identify the PCI manufacturer and device id and bus:dev:func number of the device using the lspci command. In addition, processors may have more than one PCI controller and in Linux a PCI "domain" identifies the PCI controller involved. The domain number can be determined from sysfs.

Example:

```
# lspci -nn
00:00.0 PCI bridge [0604]: Freescale Semiconductor Inc Device [1957:0410] (rev 10)
01:00.0 Ethernet controller [0200]: Intel Corporation 82574L Gigabit Network Connection [8086:10d3]

# ls /sys/bus/pci/devices/
0000:00:00.0  0000:01:00.0
```

In this example, to assign the Ethernet controller the needed information is:

- manufacturer/device-id: 8086:10d3
- bus:dev:func: 01:00.0
- domain: 0x0000

Step 2. Disable D3 state switching: From Linux-v4.1 onwards there is a feature added on switching devices into their D3 state when they are not in use but on some platforms and devices switching D3 state does not work and we need to disable D3 state. Use below command to disable D3 state switching:

```
# echo 1 > /sys/module/vfio_pci/parameters/disable_idle_d3
```

Step 3. Unbind the device from the host kernel. In order to assign the device to the virtual machine it is necessary to explicitly unbind the device from the host Linux kernel so that the device will no longer be in use by a host Linux device driver. To do this echo the *bus:dev:func* into the *unbind* file in sysfs for the PCI device. Example:

```
# echo 0000:01:00.0 > /sys/bus/pci/devices/0000:01:00.0/driver/unbin
```

Step 4. Bind the PCI device to vfio. This step signals the Linux vfio subsystem to start handling device driver functions for the manufacturer and device type of the device. This action triggers a rescan of the PCI bus and results in the device being bound to vfio. Example:

```
# echo 0001:01:00.0 > /sys/bus/pci/drivers/vfio-pci/bind
```

The echo into the new_id file in sysfs tells vfio that it is to handle devices of vendor 0x8086 and device ID 0x10d3.

Step 5. Launch QEMU.

Launch QEMU with the **-device vfio-pci** argument specifying the *domain:bus:dev:func* for the assigned device. It is required that the **mem-path** argument be used to specify hugetlbfs memory allocation. The syntax of the vfio-pci argument is:

```
-device vfio-pci,host=[domain:bus:dev:func]
```

```
Where: domain - identifies the PCI domain bus - specifies the bus number dev - specifies the PCI
device number func - specifies the device function number
```

e500mc Example:

```
qemu-system-ppc -m 512 [...] -device vfio-pci,host=0000:01:00.0 -mem-path /var/lib/hugetlbfs/
pagesize-4M
```

11.2.5.3.7 Using KVM/QEMU with libvirt

Libvirt is an open source toolkit that enables the management of Linux-based virtualization technologies such as KVM/QEMU virtual machines and Linux containers.

See the chapter ***Libvirt Users Guide*** (section under Linux User Space) for an overview of libvirt and its capabilties, features, and basic usage information.

The libvirt users guide describes the lifecycle of a virtual machine being managed by libvirt. To manage a KVM/QEMU virtual machine as a libvirt domain, it is first defined in an XML file and then a "define" operation (such as **virsh define**) is used to make libvirt aware of the domain. The domain can then be started, which causes QEMU to be invoked to boot the virtual machine. Libvirt tools can then be used to manage the running domain.

Libvirt URIs

To manage KVM/QEMU domains in libvirt, a QEMU URI is used:

- For a local node: *qemu:///system*
- For a remote node: *qemu[+transport]:///[hostname]/system*

See the libvirt users guide for more information on URIs.

Creating a KVM/QEMU Domain

The recommended procedure for creating a KVM/QEMU domain is to:

1. Identify the QEMU command line that fully specifies the desired capabilities and image to boot the virtual machine. Place the command line in a text file, including the full path to the QEMU executable and any images.
2. Convert the QEMU command line to libvirt XML with the *virsh domxml-from-native* command.
3. Use *virsh define* and *virsh start* to define and start the domain.

See Libvirt KVM/QEMU Example (Power Architecture) on page 2367 for an example of creating and managing a KVM/QEMU domain.

See Libvirt KVM/QEMU -- Adding Devices Example (Power Architecture) on page 2369 for an example of assigning devices to a KVM/QEMU domain.

Managing libvirt Domains

See the libvirt users guide for more information on URIs.

A running domain can then be managed by virsh (or other libvirt compatible development tools). Below are some examples of supported management operations:

- *virsh console* - connects to the console of the VM
- *virsh suspend* - suspends a running VM. After *suspend* the domain is in the "paused" state.
- *virsh resume* - resumes a suspended domain. After *resume* the domain is in the "running" state
- *virsh list* - lists active and running VMs
- *virsh reset* - resets the VM
- *qemu-monitor-command* - allows interactions with a VMs QEMU monitor

Libvirt XML

As described above the *virsh domxml-from-native* command is used to convert a QEMU command line into a libvirt XML file.

The full definition of the XML format and all XML tags is specified at: http://libvirt.org/formatdomain.html

11.2.5.3.8 VMs and the Linux Scheduler

Each virtual machine appears to the host Linux as a process with each virtual CPU in the VM implemented as a thread. A VM appears as an instance of QEMU when looking at Linux processes as can be seen in the example below:

```
$ ps -ef
                o
                o
 2814 root      2856 S    -/bin/sh
 2830 root      2872 S    -/bin/sh
 2831 root      595m S    ../images/qemu-system-ppc -enable-kvm -nographic -
 2838 root      2640 S    telnetd
 2839 user      3372 S    -sh
 2840 root      2864 S    -sh
                o
                o
```

CPUs appear as threads. To see thread IDs use the `info cpus` command in the QEMU monitor. Example of a VM with 4 virtual CPUs:

```
(qemu) info cpus
* CPU #0: nip=0x00000000c001451c thread_id=1977
  CPU #1: nip=0x00000000c001451c thread_id=1978
  CPU #2: nip=0x00000000c001451c thread_id=1979
  CPU #3: nip=0x00000000c001451c thread_id=1980
```

To see the QEMU threads using the ps command:

```
# ps -eL | grep qemu
 1976  1976 ttyS0    00:00:00 qemu-system-ppc
 1976  1977 ttyS0    00:00:02 qemu-system-ppc
 1976  1978 ttyS0    00:00:01 qemu-system-ppc
 1976  1979 ttyS0    00:00:06 qemu-system-ppc
 1976  1980 ttyS0    00:00:01 qemu-system-ppc
```

Being a Linux thread means that standard Linux mechanisms can be used to control aspects of how the threads are scheduled relative to other threads/processes. These mechanisms include:

- process priority
- CPU affinity
- isolcpus
- cgroups

11.2.5.4 Virtual machine reference

11.2.5.4.1 VM Overview

In general the architecture of KVM/QEMU is such that few changes should be needed to guest software to run in a VM-- i.e. a full virtualization approach is used, which means that virtual CPUs and virtual I/O devices behave like the physical hardware they are emulating.

However, there are some differences between virtual machines and native hardware that should be considered when targeting an OS to a KVM virtual machine. These differences can be divided into 3 general categories that will be discussed in further detail in this section:

1. Initial state and boot
2. CPUs
3. I/O devices

11.2.5.4.2 Memory Map of Virtual I/O Devices

The ppce500 VM contain a small subset of the devices found on an SoC. The available devices will be represented in the device tree passed to the guest at boot. See the table below for a summary of the virtual I/O devices in the ppce500 VM:

Table 585.

Virtual I/O Devices for ppce500	
ppce500v2 Address	**Descriptions**
0xe0004500	UART
0xe0040000	MPIC
0xe00e0000	Global utilities. This device is used for guest initiated reset of the VM.
0xe0008000	PCI controller. The virtual PCI bus is used for other virtual I/O devices such as virtual network and block devices.
0xe1000000	PCI IO space

11.2.5.4.3 Virtual machine state at initialization

11.2.5.4.3.1 Initial State and Boot

KVM/QEMU are compliant with the ePAPR [2] which specifies the interface between a boot program and an OS. QEMU acts as a boot program and thus the ePAPR defines the initial state of a VM.

It is recommended that a guest OS be minimally device tree aware. The libfdt library (available with the DTC tool) provides a full range of APIs to parse and manipulate device trees and will make the process of adding device tree awareness to an OS straightforward.

If the partition has multiple CPUs in it, the multi-CPU boot mechanisms specified by the ePAPR must be used to release secondary CPUs.

11.2.5.4.3.2 Initial Mapped Areas

The ePAPR [2] defines the concept of an *initial mapped area* or IMA. A partition's IMA is the region of memory mapped in the MMU by the boot program that contains the entry point for the guest. Both boot CPUs and secondary CPUs begin client

program execution in an IMA. The terms *Boot IMA* and *Secondary IMA* are used to distinguish the IMAs for boot CPUs and secondary CPUs where necessary.

11.2.5.4.3.2.1 Boot IMA

By default QEMU will set up a boot IMA that spans the OS kernel image and device tree. As per the ePAPR, the MMU will be configured with the effective address of the boot IMA to be 0x0.

The size of the boot IMA is passed to the client in r7 as per the ePAPR.

11.2.5.4.3.2.2 Secondary IMA

The guest physical address of secondary IMAs can be determined by the **entry_addr** field in the spin table used to release secondary vcpus. The effective address will be 0x0. The secondary IMA will always be 4KiB in size.

11.2.5.4.3.3 Initial State of Virtual CPUs

In a VM with multiple virtual CPUs, CPU #0 is the boot CPU and all other vcpus in the partition are considered secondary. See the ePAPR for additional details on boot and secondary CPUs.

11.2.5.4.3.3.1 CPU Initial State

Within a partition, the initial state of the boot and secondary vcpus complies with the entry conditions specified in the ePAPR. The virtual CPU state is summarized below:

Table 586. vcpu Initial State

Register	Value
MSR	PR=0, supervisor state EE=0, interrupts disabled ME=0, machine check interrupt disabled CE=0, critical interrupts disabled GS=1, guest state (if host CPU implements category E.HV)
R3	For boot CPUs will be effective address of the guest device tree image. For secondary CPUs will be value of R3 field in the ePAPR spin table.
R4	0
R5	0
R6	For boot CPUs: ePAPR magic value-0x45504150 For secondary CPUs: zero.
R7	Size of the boot or secondary IMA
R8	0
R9	0
R10-R31	undefined

Table continues on the next page...

Table 586. vcpu Initial State (continued)

Register	Value
F0-F31	undefined (floating point registers)
TCR	WRC=0, no watchdog timer reset will occur WIE=0, watchdog timer interrupt disabled FIE=0, fixed interval timer disabled DIE=0, decrementer interrupt disabled
PIR	Contains the partition-relative CPU index for the current CPU.
other registers	Undefined
TLB	Has a mapping for the IMA as per the ePAPR. The initial mapping will be in TLB1.

11.2.5.4.3.3.2 Secondary CPUs

At partition start, all secondary vcpus are in a quiescent state and spinning in the spin-table as per the ePAPR. They can be released from the spin by writing the location specified in the *cpu-release-addr* property in the guest device tree as defined in the ePAPR.

Vcpus do not support a writeable PIR register and thus the *pir* field in the spin table is not supported.

11.2.5.4.3.4 Initial State of I/O Devices

The initial state of direct mapped I/O devices is undefined, except that all interrupt sources have interrupts masked at the virtual MPIC.

11.2.5.4.4 Virtual CPUs

11.2.5.4.4.1 Virtual CPU Specification

Software running in a virtual machine sees a virtual CPU that emulates an e500 CPU. The behavior of instructions, registers, and exceptions on the vcpu is nearly identical to the physical CPU being emulated.

The virtual CPU type will match that of the host hardware platform. On an e500mc system, the vcpu looks like an e500mc CPU, and the same will be true for e5500, and e6500 CPUs.

Differences between the vcpu and emulated CPU are defined in the *NXP Power Architecture Book E Virtual CPU Specification* [3].

See the KVM/QEMU release notes for any specific limitations in CPU features supported for a given release of KVM/QEMU.

11.2.5.4.4.2 Time in the Virtual CPU

Guest software is able to directly read the physical timebase registers of the CPU without hypervisor mediation. This means the VM's view of time with respect to the timebase is real, wall clock time. However, since a VM may share physical CPUs with other Linux processes the actual time the VM runs is some percentage of the available CPU time.

Suppose a VM performs a task for 50 ms and receives 50% of the physical CPU time. In this case the VM would get approximately 25 ms of work on the task done during an elapsed time of 50ms. Time appears to have been 'stolen' from the VM. There is no mechanism currently available for a VM to determine how much time is being stolen.

The decrementer in the vcpu operates in terms of real, wall clock time. A decrementer timeout of 100 ms will occur in 100 ms of wall clock time. But note, there may be additional jitter to the decrementer timeout because of other processes or VMs that share the CPU.

11.2.5.4.4.3 VCPU Watchdog

The vcpu in the e500mc, e5500 and e6500 VMs has a standard e500 watchdog timer.

When a final watchdog expiration occurs, and if TCR[WRC] is non-zero, the QEMU command line argument **-watchdog-action** controls the policy.

From the QEMU User's Manual [1]:

- The **action** controls what QEMU will do when the watchdog timer expires. The default is **reset** (forcefully reset the guest).
- Other actions are **poweroff** (exits QEMU), **pause** (pause the guest), **debug** (print a debug message and continue), or **none** (do nothing).
- The **shutdown** action is not supported.

11.2.5.4.5 Virtual MPIC

The virtual MPIC is used to manage device interrupts to the VM. The virtual MPIC implements a subset of the functionality of the standard MPIC interrupt controller found on e500-based SoCs. The implemented subset is the functionality needed to manage interrupts.

The following MPIC features are not implemented:

- Global timers
- MSIs
- Message interrupts
- Performance monitor mask registers
- Configuring sources as critical or machine check

Accesses made to unimplemented registers are ignored.

Guest software does not need to do a readback from the virtual MPIC after writing EOI. This is needed in hardware on some implementations (particularly with external proxy), but under KVM it is a wasteful trap. Likewise, under KVM, no read-back is required after masking an interrupt before it takes effect.

The table below shows the implemented registers with differences between the hardware MPIC noted.

Table 587. Virtual MPIC Registers

Global Registers			
Offset	**Register**	**Access**	**Notes**
0x4_0080	CTPR-Current task priority register	RW	
0x4_0090	WHOAMI-Who am I register	R	
0x4_00A0	IACK-Interrupt acknowledge register	R	
0x4_00B0	EOI-End of interrupt register	W	
0x4_1000	FRR-Feature reporting register	R	

Table continues on the next page...

Table 587. Virtual MPIC Registers (continued)

Global Registers			
Offset	**Register**	**Access**	**Notes**
0x4_1020	GCR-Global configuration register	RW	Only the RST bit is implemented which resets the MPIC.
0x4_1080	VIR-Vendor identification register	R	VIR is always 0x0
0x4_1090	PIR-Processor core initialization register	R	Not supported
0x4_10E0	SVR-Spurious vector register	RW	Initial value is 0xffff.
Global Timer Registers			
	Note: Only the interrupt source configuration registers for the global timers are implemented-the global timers are not implemented.		
0x4_1120	GTVPRA0 - timer A0 vector/priority register	RW	
0x4_1130	GTDRA0 - timer A0 destination register	RW	
0x4_1160	GTVPRA1 - timer A1 vector/priority register	RW	
0x4_1170	GTDRA1- timer A1 destination register	RW	
0x4_11A0	GTVPRA2- timer A2 vector/priority register	RW	
0x4_11B0	GTDRA2- timer A2 destination register	RW	
0x4_11E0	GTVPRA3- timer A3 vector/priority register	RW	
0x4_11F0	GTDRA3- timer A3 destination register	RW	
0x4_2120	GTVPRA0 timer A0 vector/priority register	RW	
0x4_2130	GTDRA0 timer A0 destination register	RW	
0x4_2160	GTVPRA1 timer A1 vector/priority register	RW	
0x4_2170	GTDRA1 timer A1 destination register	RW	
0x4_21A0	GTVPRA2 timer A2 vector/priority register	RW	
0x4_21B0	GTDRA2 timer A2 destination register	RW	
0x4_11E0	GTVPRA3 timer A3 vector/priority register	RW	
0x4_11F0	GTDRA3 timer A3 destination register	RW	

Table continues on the next page...

Table 587. Virtual MPIC Registers (continued)

Global Registers			
Offset	**Register**	**Access**	**Notes**
Interrupt Source Configuration Registers			
0x5_0000	Interrupt source 0 vector/priority register	RW	
0x5_0010	Interrupt source 0 destination register	RW	
0x5_0020	Interrupt source 1 vector/priority register	RW	
0x5_0030	Interrupt source 1 destination register	RW	
0x5_0040 - 0x5_fff0	Interrupt source 2 through interrupt source 2048 configuration registers.	RW	
Per-CPU Registers			
0x6_0080	CTPR-Current task priority register	RW	
0x6_0090	WHOAMI-Who am I register	R	
0x6_00A0	IACK-Interrupt acknowledge register	R	
0x6_00B0	EOI-End of interrupt register	W	

The device tree node for the virtual MPIC is shown below.

```
pic@40000 {
        clock-frequency = <0>;
        interrupt-controller;
        #address-cells = <0>;
        #interrupt-cells = <4>;
        reg = <0x40000 0x40000>;
        compatible = "fsl,mpic", "chrp,open-pic";
        device_type = "open-pic";
        big-endian;
};
```

11.2.5.4.6 Virtual PCI

The virtual PCI controller and bus are used for virtual devices such as virtual network devices, virtual block devices, virtual USB controller, etc. The virtual PCI controller implements a subset of the functionality of the PCI controller sufficient for an unmodified guest PCI device driver to probe the virtual PCI bus.

The table below shows the implemented registers.

Table 588. Virtual PCI Controller Registers

PCI Configuration Access Registers			
Offset	**Register**	**Access**	**Notes**
0x000	CFG_ADDR-PCI configuration address	RW	
0x004	CFG_DATA-PCI configuration data	RW	
PCI Express ATMU Registers			
0xC20 - 0xDF0	Outbound Windows 1 - 4 and Inbound Windows 1 - 4.	RW	The translation address, translation extended address, base address, and window attribute registers for outbound and inbound windows 1 - 4 can be read and written, but perform no function.

11.2.5.4.7 Virtual UART

The virtual machine implements a standard ns16550 UART which can be used by guest software for character I/O.

Table 589. Virtual UART Registers

Block Base Address (Address: 0x11c500)			
Offset	**Register**	**Access**	**Notes**
0x00	URBR-ULCR[DLAB] = 0 , Receiver buffer register	R	
0x00	UTHR-ULCR[DLAB] = 0, Transmitter holding register	W	
0x00	UDLB-ULCR[DLAB] = 1, Divisor least significant byte register	RW	
0x01	UIER-ULCR[DLAB] = 0, Interrupt enable register	RW	
0x01	UDMB-ULCR[DLAB] = 1, Divisor most significant byte register	RW	
0x02	Interrupt ID register	R	
0x02	FIFO control register	W	
0x03	Line control register	RW	
0x04	Modem control register	RW	
0x05	Line status register	R	

Table continues on the next page...

Table 589. Virtual UART Registers (continued)

Block Base Address (Address: 0x11c500)			
Offset	**Register**	**Access**	**Notes**
0x06	Modem status register	R	
0x07	Scratch register	RW	

The device tree node for the virtual UART is shown below.

```
serial@11c500 {
        cell-index = <0>;
        device_type = "serial";
        compatible = "ns16550";
        reg = <0x11c500 0x100>;
        clock-frequency = <0>;
        interrupts = <36 2 0 0>;
};
```

11.2.5.4.8 Virtual Global Utilities

A reset of a virtual machine is done via the reset control register in an emulated global utilities device. The supported registers in the global utilities are shown in the table below.

Table 590. Virtual Global Utilities Registers

Global Utilities			
Offset	**Register**	**Access**	**Notes**
Version Registers			
0xE_00A0	PVR-Processor version register	R	
0xE_00A4	SVR-System version register	R	
Status Registers			
0xE_00B0	RSTCR-Reset control register	W	A value of 0x2 will cause a virtual machine reset.

The device tree node for the virtual GUTS is shown below.

```
global-utilities@e0000 {
        compatible = "fsl,guts-rstcr";
        reg = <0xe0000 0x1000>;
        fsl,has-rstcr;
};
```

11.2.5.5 Debugging virtual machines

11.2.5.5.1 QEMU Monitor

When starting QEMU, a monitor shell is available that can be used to control and see the state of VM. By default this monitor is started in the Linux shell where QEMU is invoked.

See example below of the output when starting QEMU. The user can interact with the monitor at the (qemu) prompt.

```
QEMU waiting for connection on: telnet::0.0.0.04445,server
QEMU 2.2.0 monitor - type 'help' for more information
(qemu)
```

The monitor can also be exposed over a network port by using the `-monitor dev` command line option. See Overview of Using QEMU on page 2338 and the QEMU user's manual [1] (see References on page 2333).

Refer to the QEMU user's manual [1] for a complete listing of the monitor commands available. Below is a list of some useful commands supported in the NXP SDK implementation of QEMU:

- **help** - lists all the available commands with usage information
- **info cpus** - displays the state and thread ID of all virtual CPUs
- **info** *registers* - displays the contents of the default vcpu's registers
- **cpucpu_number** - sets the default vcpu number
- **info** *tlb* - displays the vcpu's TLBs
- **system_reset** - resets the VM
- **x**/*fmt addr* -- virtual memory dump starting at 'addr'
- **xp**/*fmt addr* -- physical memory dump starting at 'addr'

11.2.5.5.2 QEMU GDB Stub

QEMU supports debugging of a VM using gdb. QEMU contains a gdb stub that can be attached to from a host system and allows standard source level debugging capabilities to examine the state of the VM and do run control.

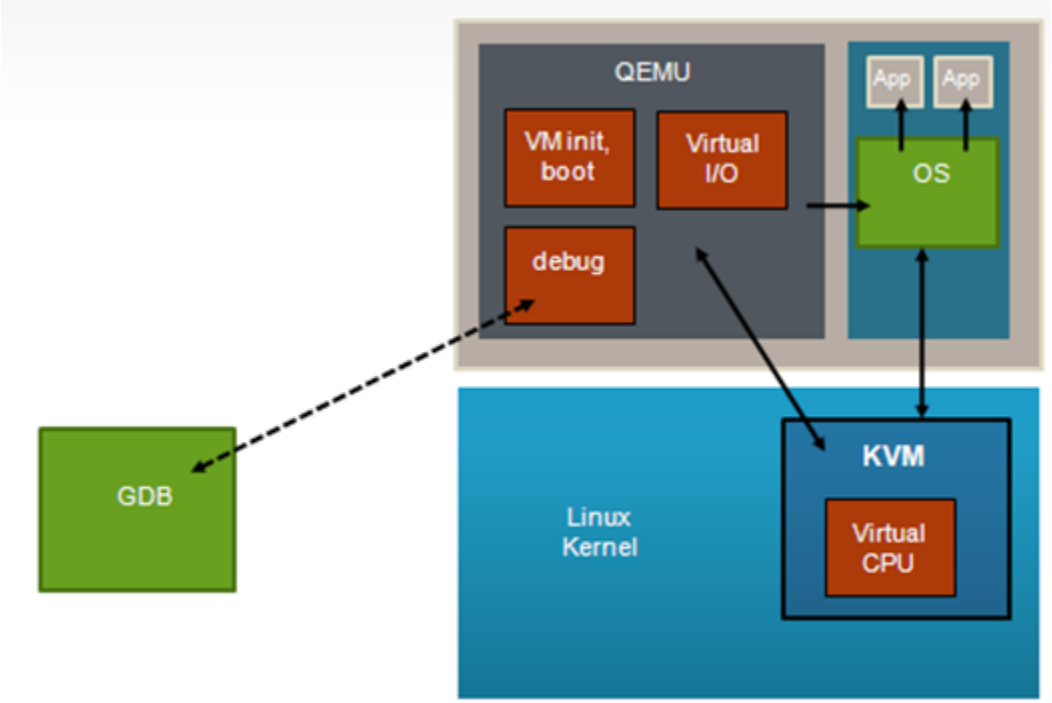

Figure 372.

To use the gdb stub, start QEMU with the -gdb *dev* option where dev specifies the type of connection to be used. See the QEMU user's manual [1] (see References on page 2333) for details.

One useful option when debugging is the -S argument to QEMU which causes QEMU to wait to start the first instruction of the guest until told to start using the monitor (**continue** command).

In the example below the tcp device type is used. A gdb stub will be active on port 4445 of the host Linux kernel when starting QEMU:

```
$ qemu-system-ppc -enable-kvm -nographic -M ppce500 -kernel uImage-p4080ds.bin -initrd devel-
image-p4080ds.ext2.gz -append "root=/dev/ram rw console=ttyS0,115200" -serial tcp::
4444,server,telnet -gdb tcp::4445

QEMU waiting for connection on: telnet::0.0.0.04444,server
QEMU 2.2.0 monitor - type 'help' for more information
(qemu)
```

After the guest has been started normally, gdb can be used to connect to the VM (in this example the host kernel has an ip address of 192.168.1.43):

```
(gdb) target remote 192.168.1.43:4445
Remote debugging using 192.168.1.43:4445
0xc000db38 in ?? ()
```

Debugging with gdb can then proceed normally:

```
(gdb) p/x $r3
$1 = 0xc075a000
```

11.2.5.6 KVM/QEMU How-to's

11.2.5.6.1 Quick-start Steps to Build and Deploy KVM Using Yocto

The following steps show how to build host and guest root filesystems, Linux kernel, and QEMU in the Yocto environment.

There are two possibilities to deploy KVM using Yocto:

- Using the preconfigured **fsl-image-virt** Yocto image as the base for host root filesystem. This image type will generate a host root filesystem which contains: QEMU, guest root filesystem and guest kernel image.
- Using other Yocto images as the base for host rootfilesystem . If the user wants to use other Yocto images to enable KVM there will be additional steps needed in order to add all the needed pieces into the host root filesystem: QEMU, guest root filesystem, guest kernel image.

11.2.5.6.1.1 Deploy KVM using fsl-image-virt Image

The host roofs is based on the **fsl-image-virt** image type and the guest rootfs is based on **fsl-image-core**.

The steps outlined below assume that the Yocto build environment is configured so that the **bitbake** command can be run.

1. Build the base host root filesystem using the **fsl-image-virt** image type.

   ```
   $ bitbake fsl-image-virt
   ```

2. Build a kernel with KVM enabled. In this case the same kernel image will be used for both host and guest.

   Configure the Linux kernel to enable KVM-related features.

   ```
   $ bitbake -c menuconfig virtual/kernel
   ```

   Follow the steps described in section Quick Start - Recommended Configuration Options on page 2335 to enable KVM in the Linux kernel.

   Then rebuild the kernel based on the new configuration options:

   ```
   $ bitbake virtual/kernel
   ```

3. Re-build the fsl-image-virt image.

   ```
   bitbake fsl-image-virt
   ```

   The resulting host rootfs will contain:

   - Linux kernel image
   - Guest root filesystem: based on **fsl-image-core**
   - QEMU

For steps to run QEMU see the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2359.

11.2.5.6.1.2 Deploy KVM using fsl-image-core Image

The host roofs is based on the **fsl-image-core** image type and the guest rootfs is based on **fsl-image-minimal**.

The steps outlined below assume that the Yocto build environment is configured so that the **bitbake** command can be run.

1. Build the base host root filesystem using the **fsl-image-core** image type.

   ```
   $ bitbake fsl-image-core
   ```

2. Build a host kernel with KVM-enabled.

   Configure the Linux kernel to enable KVM-related features.

   ```
   $ bitbake -c menuconfig virtual/kernel
   ```

   Follow the steps described in section Quick Start - Recommended Configuration Options on page 2335 to enable KVM in the Linux kernel.

   Then rebuild the kernel based on the new configuration options:

   ```
   $ bitbake virtual/kernel
   ```

3. Add QEMU to the packages built by **fsl-image-core**.

   Edit the `conf/local.conf` file and append the following line which adds the QEMU package:

   ```
   IMAGE_INSTALL_append = " qemu"
   ```

4. Build a guest root filesystem and add it to the host rootfs.

   A. Build the guest roofs using the **fsl-image-minimal** image type. This creates a small rootfs sufficient for booting a Linux guest:

   ```
   $ bitbake fsl-image-minimal
   ```

   This command results in the minimal rootfs being created in tmp/deploy/images. In this example the minimal rootfs built is named: fsl-image-minimal.rootfs.ext2.gz

   B. Use the merge-files feature of Yocto (see Adding Images to a Root Filesystem with Yocto on page 2338) to copy the guest rootfs to the host rootfs.

   ```
   $ mkdir -p ../sources/meta-freescale/recipes-extended/merge-files/merge/home/root

   $ cp tmp/deploy/images/<platform>/fsl-image-minimal.rootfs.ext2.gz ../sources/meta-freescale/
   recipes-extended/merge-files/merge/home/root/guest.rootfs.ext2.gz

   $ bitbake -c install -f merge-files

   $ bitbake merge-files
   ```

5. Re-build the fsl-image-core image.

   ```
   bitbake fsl-image-core
   ```

   The resulting host rootfs will contain:

   - Linux kernel image
   - Guest root filesystem
   - QEMU, including the example guest device trees

For steps to run QEMU see the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2359.

11.2.5.6.2 Quick-start Steps to Run KVM Using Hugetlbfs

The pre-requisite to this example is completing the steps in the article Quick-start Steps to Build and Deploy KVM Using Yocto on page 2357.

This example assumes that the host Linux kernel is booted, has a working network interface, and the following images are present in the host root filesystem:

- Guest kernel image (/boot/uImage)
- Guest root filesystem (/home/root/guest.rootfs.ext2.gz)
- QEMU (/usr/bin/qemu-system-ppc or qemu-system-ppc64)

There are a number of mechanisms for allocating huge pages and making them accessible via a mount point. Refer to the SDK documentation for details. This example assume allocating pages using the hugeadm command. Create a 1GB pool of 4MB huge pages, which can be used by QEMU for allocating VM memory:

```
$ hugeadm --pool-pages-min 4M:256

$ hugeadm --pool-list
      Size  Minimum  Current  Maximum  Default
   1048576        0        0        0
   4194304      256      256      256        *
  16777216        0        0        0
  67108864        0        0        0
 268435456        0        0        0
1073741824        0        0        0
```

Create a mount point to access the huge pages:

```
$ hugeadm --create-mounts

$  ls -1 /var/lib/hugetlbfs/
pagesize-16MB
pagesize-1GB
pagesize-256MB
pagesize-4MB
pagesize-64MB
```

Start QEMU specifying the 4MB huge page pool as the file from which to allocate memory. In this example 512MB of memory is allocated to the VM:

```
$ qemu-system-ppc -enable-kvm -m 512 -mem-path /var/lib/hugetlbfs/pagesize-4MB -nographic -M
ppce500 -kernel /boot/uImage -initrd ./guest.rootfs.ext2.gz -append "root=/dev/ram rw
console=ttyS0,115200" -serial tcp::4444,server,telnet

QEMU waiting for connection on: telnet::0.0.0.04444,server
```

Explanation of the command line options:

- **-enable-kvm** : specifies that KVM should be used
- **-m 512** : the amount of memory for the VM
- **-mem-path /var/lib/hugetlbfs/pagesize-4MB** : allocates from hugetlbfs based memory
- **-nographic** : don't instantiate a graphics card, this is the only option supported for the SDK
- **-M ppce500** : the type of virtual machine
- **-kernel /boot/uImage** : name of guest Linux kernel

- **-initrd ./guest.rootfs.ext2.gz** : name of guest roofs
- **-append "root=/dev/ram rw console=ttyS0,115200"** : guest Linux bootargs
- **-serial tcp::4444,server,telnet** : provide an emulated serial port (telnet server) on port 4444 on the host Linux system. Default behavior will be for QEMU to wait until the user connects to this port before booting the VM.

At this point QEMU is waiting for a telnet connection to the virtual machine's console (port 4444 of the target board) prior to starting the virtual machine.

Connect to QEMU via telnet to start the virtual machine booting. In this example the target board has IP address 192.168.1.234.

```
$ telnet 192.168.1.234 4444

11.2.5.6.3 How to Use Virtual Network Interfaces Using Virtio

As discussed in Virtual network interfaces on page 2342, there are two aspects of virtual network interfaces-- 1) the "front end" (the device as seen by the guest OS) and 2) the "backend" (the means by the virtual device is connected to the network).

This example uses a "virtio" model NIC card and a tap network backend. The virtual network interface is bridged via a TAP interface to the physical network. The guest OS is Linux.

When starting QEMU we will add the following arguments to create the virtual network interface:

```
-netdev tap,id=tap0,script=/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -device
virtio-net-pci,netdev=tap0
```

Perform the following steps:

1. Enable virtio networking in the host and guest Linux kernels (see Host Kernel: Enabling Virtual Networking on page 2336 and Guest Kernel: Enabling Network and Block Virtual I/O on page 2337).
2. On the host Linux create a bridge to the physical network interface to be used by the virtual network interface in the virtual machine using the **brctl** command. In this example the physical interface being used is fm1-gb1:

   ```
   $ brctl addbr br0
   $ ifconfig br0 192.168.1.139
   $ ifconfig fm1-gb1 up
   $ brctl addif br0 fm1-gb1
   ```

3. Create a qemu-ifup script on the host Linux system. For the TAP backend type, when QEMU creates the virtual network interface it invokes a user-created script that allows customization of how the TAP interface is to be handled.

The name of the TAP interface created by QEMU is passed as an argument. In this example we will bridge the the TAP inteface to the bridge created in step #2. See the example qemu-ifup script below:

```
#!/bin/sh
# TAP interface will be passed in $1
bridge=br0
guest_device=$1
ifconfig $guest_device up
brctl addif $bridge $guest_device
```

4. In order to have a smooth experience when stopping/restarting the virtual machine, you should also create a symmetrical qemu-ifdown script, that will remove the TAP interface from the bridge once the guest stops. This is not mandatory, but if it's not specified, QEMU will issue a warning on guest exit. Similarly, the name of the TAP interface created by QEMU is passed as an argument.

```

# TAP interface will be passed in $1
bridge=br0
guest_device=$1
ifconfig $guest_device down
brctl delif $bridge $guest_device
```

5. When starting QEMU specify that the network device type is "virtio" and specify the path to the script created in step #3:

```
qemu-system-ppc -enable-kvm -nographic -m 256 -M ppce500 -kernel uImage -initrd rootfs.ext2.gz -
append "root=/dev/ram rw console=ttyS0,115200"  -serial tcp::4444,server -netdev
tap,id=tap0,script=/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -device virtio-
net-pci,netdev=tap0
```

6. In the guest OS the virtual network interface will appear and can be brought up and assigned an IP address in the normal way. In the example below (the commands are run from the guest command shell) the virtio interface is eth0.

```

$ ip addr
1: lo: <LOOPBACK,UP,LOWER_UP> mtu 16436 qdisc noqueue
    link/loopback 00:00:00:00:00:00 brd 00:00:00:00:00:00
    inet 127.0.0.1/8 scope host lo
    inet6 ::1/128 scope host
       valid_lft forever preferred_lft forever
2: dummy0: <BROADCAST,NOARP> mtu 1500 qdisc noop
    link/ether 1e:6e:b8:9a:81:32 brd ff:ff:ff:ff:ff:ff

$ ethtool -i eth0
driver: virtio_net
version:
firmware-version:
bus-info: virtio0

$ ifconfig eth0 192.168.1.126
```

11.2.5.6.4 How to Use Virtual Disks Using Virtio

As discussed in Virtual block devices on page 2342, there are a number of formats available for virtual disk images.

The example below uses a raw file. The steps below go through the process of creating a virtual disk image, assigning it to a VM, partitioning the disk, creating a filesystem on it, and mounting it.

1. On the host Linux, create a binary image to represent the guest disk. For example to create a 16MB disk:

```
$ dd if=/dev/zero of=my_guest_disk bs=4K count=4K
```

2. Start QEMU, specifying the name of the virtual disk file for the -drive argument:

```
$ qemu-system-ppc -enable-kvm -nographic -m 256 -M ppce500 -kernel uImage
-initrd rootfs.ext2.gz -append "root=/dev/ram rw console=ttyS0,115200"
-serial tcp::4444,server,telnet -drive file=my_guest_disk,cache=none,if=virtio
```

3. After the guest has booted the virtual disk is visible as a block device in /dev with the name vda, vdb, etc.

```
$ ls -l /dev/vda
brw-r-----    1 root     disk     254,   0 Jan  1 00:02 /dev/vda
```

   A virtual block device can be treated like any other hard disk. It can be partitioned, formatted, and mounted.

4. Configure a partition on the disk with fdisk:

```
$ fdisk /dev/vda
Device contains neither a valid DOS partition table, nor Sun, SGI or OSF disklabel
Building a new DOS disklabel. Changes will remain in memory only,
until you decide to write them. After that the previous content
won't be recoverable.
Command (m for help):
```

   Display the partition table:

```
Command (m for help): p
Disk /dev/vda: 16 MB, 16777216 bytes
16 heads, 63 sectors/track, 32 cylinders
Units = cylinders of 1008 * 512 = 516096 bytes
   Device Boot      Start         End      Blocks  Id System
Command (m for help):
```

   Create a new partition:

```
Command (m for help): n
Command action
   e   extended
   p   primary partition (1-4)
p
Partition number (1-4): 1
First cylinder (1-32, default 1): 1
Last cylinder or +size or +sizeM or +sizeK (1-32, default 32): Using default value 32
Command (m for help):
```

   Display the new partition:

```
Command (m for help): p
Disk /dev/vda: 16 MB, 16777216 bytes
16 heads, 63 sectors/track, 32 cylinders
```

```
Units = cylinders of 1008 * 512 = 516096 bytes
   Device Boot      Start         End      Blocks  Id System
/dev/vda1               1          32       16096+ 83 Linux
Command (m for help)
```

Write the partition table to disk and exit:

```
Command (m for help): w
The partition table has been altered!
Calling ioctl() to re-read partition table
 vda: vda1
```

5. Create a filesystem on the new partition:

```
$ mkfs.ext3 /dev/vda1
mke2fs 1.41.4 (27-Jan-2009)
Filesystem label=
OS type: Linux
Block size=1024 (log=0)
Fragment size=1024 (log=0)
4032 inodes, 16096 blocks
804 blocks (5.00%) reserved for the super user
First data block=1
Maximum filesystem blocks=16515072
2 block groups
8192 blocks per group, 8192 fragments per group
2016 inodes per group
Superblock backups stored on blocks:
        8193
Writing inode tables: done
Creating journal (1024 blocks): done
Writing superblocks and filesystem accounting information: done
This filesystem will be automatically checked every 35 mounts or
180 days, whichever comes first.  Use tune2fs -c or -i to override.
```

6. Mount the filesystem:

```
$ mount /dev/vda1 /mnt/src
EXT3-fs: barriers not enabled
kjournald starting.  Commit interval 5 seconds
EXT3-fs (vda1): using internal journal
EXT3-fs (vda1): mounted filesystem with writeback data mode
```

11.2.5.6.5 Debugging: How to Examine Initial Virtual Machine State with QEMU

It can be helpful when debugging to examine the state of the virtual machine prior to executing the first instruction of the guest OS.

To do this, start QEMU with the -S option.

Example:

```
qemu-system-ppc -enable-kvm -nographic -m 256 -M ppce500 -kernel uImage -initrd rootfs.ext2.gz -
append "root=/dev/ram rw console=ttyS0,115200"  -serial tcp::4444,server,telnet -S
```

The console was started with the "-serial tcp::4444,server,telnet" option so QEMU waits for a connection prior to starting initialization. Use telnet to connect to port 4444 of the target.

At this point QEMU initializes the VM, but does not execute the entry point to the guest OS. The monitor prompt can now be used to examine initial state:

```
CQEMU waiting for connection on: telnet::0.0.0.04444,server
QEMU 1.4.0 monitor - type 'help' for more information
(qemu)
```

In this example, the VM was assigned direct-mapped memory at physical address 0x40000000.

To see where boot images are loaded and placed by QEMU use the **info roms** command:

```
(qemu) info roms
addr=0000000000000000 size=0x857540 mem=ram name="uImage"
addr=0000000002000000 size=0x010000 mem=ram name="mpc8544ds.dtb"
addr=0000000003000000 size=0x5782aa8 mem=ram name="rootfs.ext2.gz"
```

The kernel image (uImage) is loaded at the start of guest memory at 0x00000000. The guest device tree is loaded at 0x40c00000. The ramdisk is loaded at 0x42000000.

To examine the initial state of the TLBs use the **info tlb** command:

```
(qemu) info tlb

TLB0:
Effective          Physical           Size TID   TS SRWX URWX WIMGE U0123

TLB1:
Effective          Physical           Size TID   TS SRWX URWX WIMGE U0123
0x0000000000000000 0x0000000000000000  64M 0     0  SRWXURWX ----- U----
```

One TLB entry is present which maps the ePAPR defined initial mapped area (IMA). As per the ePAPR the effective address of the IMA is 0x0.

To examine the initial state of registers use the info registers command:

```
(qemu) info registers
NIP 00000000   LR 00000000 CTR 00000000 XER 00000000
MSR 10000000 HID0 00000000  HF 00000000 idx 1
TB 00000501 3593879695 DECR 00000000
GPR00 0000000000000000 0000000000000000 0000000000000000 0000000000c00000
GPR04 0000000000000000 0000000000000000 0000000045504150 0000000010000000
GPR08 0000000000000000 0000000000000000 0000000000000000 0000000000000000
GPR12 0000000000000000 0000000000000000 0000000000000000 0000000000000000
GPR16 0000000000000000 0000000000000000 0000000000000000 0000000000000000
GPR20 0000000000000000 0000000000000000 0000000000000000 0000000000000000
GPR24 0000000000000000 0000000000000000 0000000000000000 0000000000000000
GPR28 0000000000000000 0000000000000000 0000000000000000 0000000000000000
CR 00000000  [ -  -  -  -  -  -  -  -  ]             RES ffffffff
```

The program counter (NIP) is set to 0x00000000 which is the effective address of the entry point of the kernel. Other registers contain initial state as defined by the ePAPR. R3 contains the address of the guest device tree. R7 contains the size of the IMA.

11.2.5.6.6 Debugging: How to Profile Virtualization Overhead with KVM

Running software in a virtual machine can cause additional overhead that affects performance. The virtualization overhead is directly related to the number of time the hypervisor (KVM) is invoked to handle exception conditions that may occur in the virtual machine. These exception handling events are referred to as 'exits', because guest context is exited.

Examples of exits include things such the guest executing a privileged instruction, access a privileged CPU register, accessing a virtual I/O device, or a hardware interrupt such as a decrementer interrupt.

The type and number of exits that occur is workload dependent.

Counting Exits

A count of a subset of KVM exits that occur can be seen under debugfs. To see this first mount debugfs:

```
mount -t debugfs none /sys/kernel/debug
```

The exit statistics can be seen under /sys/kernel/debug/kvm. A simple script (called kvm_stat in this example) can display the statistics:

```
#!/bin/bash

IFS=$(echo -en "\n\b")

for i in $(ls -1 /sys/kernel/debug/kvm/)
do
    echo -n "$i: "
    file=`echo $i | sed 's/ /\\ /g'`
    cat "/sys/kernel/debug/kvm/$file"
done
```

Example of running the kvm_stat script above:

```
# ./kvm_stat
dcr: 0
dec: 4828
doorbell: 0
dsi: 0
dtlb_r: 627339
dtlb_v: 1475
ext_intr: 87
guest doorbell: 4142
halt_wakeup: 69
inst_emu: 984745
isi: 43
itlb_r: 544461
itlb_v: 1352
mmio: 17914
sig: 0
sysc: 0
```

Getting Exit Timings

To understand the exits that occur and how much overhead (in terms of time) that they add, a kernel configuration option is available in the host kernel that makes statistics available in /sys.

To enable exit timings enable the following option in the kernel:

```
Virtualization  --->
         [*]   Detailed exit timing
```

Then boot the host kernel normally and start the virtual machine that is to be profiled.

In the host kernel mount debugfs where the exit timing statistics will be shown:

```
mount -t debugfs none /sys/kernel/debug
```

KVM related statics for each active virtual CPU can be seen under /sys/kernel/debug/kvm in a file named vm[vcpu-thread-id]_vcpu[vcpu#]_timing. For example:

```
# ls -1 /sys/kernel/debug/kvm/vm*
/sys/kernel/debug/kvm/vm1660_vcpu0_timing
/sys/kernel/debug/kvm/vm1661_vcpu1_timing
```

To see the exit timings, use the cat command on the timing file:

```
# cat /sys/kernel/debug/kvm/vm1660_vcpu0_timing

type    count   min     max     sum     sum_squared
        MMIO    14764           1      36620         199893        43199875902
         DCR        0  238609294          0              0                  0

      DEBUG        0  238609294          0              0                  0
    PERFMON        0  238609294          0              0                  0
 TIMEINGUEST  1124002           0       4161        7291506       246400568633
      DBELL     1009           1          5           2043              81017
 GUEST_DBELL     3911           0      37587         408794        60625818916
 PROGRAM_INT        0  238609294          0              0                  0
```

The first column identifies the exit counter, the second column identifies the count of exits, and the 5th column identifies total accumulated time for each exit type in nanoseconds (ns).

To zero the counters, echo the character 'c' to the exit timings file in debugfs. For example:

```
echo -n 'c' >/sys/kernel/debug/kvm/vm1660_vcpu0_timing
```

11.2.5.6.7 How to Create a uImage Format Program Image

QEMU can load OS kernel images passed using the **-kernel** command line flag. The image type supported is a uImage, which is an image format with its origins from the u-boot bootloader. A uImage is binary program image that with a 64-byte header that has information about the type of image.

This article shows how to take an ELF program image, convert it to a binary program image, and then use the mkimage utility to convert the program to a uImage format file. In this example the ELF program executable is called *hello*.

1. The first step is to create a binary image from the ELF executable using objcopy. The objcopy is available in the cross compile toolchain provided by the NXP SDK.

   ```
   ${CROSS_COMPILE}objcopy -O binary hello hello.bin
   ```

   Where $CROSS_COMPILE is the path to the cross compile toolchain.

2. Next convert the binary image to a uimage with the mkimage tool available in u-boot.

   ```
   mkimage -A ppc -T kernel -C none -a 00000000 -e 00000000 -d hello.bin hello.uimage
   ```

   The -a flag specfiies the physical address where to load the image. In this example, the load address is 0x0.

   The -e flag specifies the physical address of the entry point. In this example the entry point address is 0x0.

3. The parameters and values used in creating the uimage can be viewed with mkimage -l

   ```
   $ mkimage -l hello.uimage
   Image Name:
   Created:      Tue May 22 12:38:25 2012
   Image Type:   PowerPC Linux Kernel Image (uncompressed)
   Data Size:    49012 Bytes = 47.86 kB = 0.05 MB
   Load Address: 0x00000000
   Entry Point:  0x00000000
   ```

11.2.5.6.8 Libvirt KVM/QEMU Example (Power Architecture)

The following example shows the lifecycle of a simple KVM/QEMU libvirt domain called *kvm1*.

In this example the default URI is qemu:///system, and because of this default an explicit URI is not used in the virsh commands.

1. We begin with a simple QEMU command line in a text file named kvm1.args:

```
$ cat kvm1.args
/usr/bin/qemu-system-ppc -m 256 -nographic -M ppce500 -kernel /boot/uImage -initrd /home/root/
my.rootfs.ext2.gz -append "root=/dev/ram rw console=ttyS0,115200" -serial pty -enable-kvm -name kvm1
$
```

NOTE

The serial console is a tty, not a telnet server. The -name option is required and specifies the name of the virtual machine.

2. Before defining the domain the QEMU command line must be converted to libvirt XML format:

```
$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$
```

The content of the newly created domain XML file is shown below:

```
$ cat kvm1.xml
<domain type='kvm'>
  <name>kvm1</name>
  <uuid>f5b7cf86-41eb-eb78-4284-16501ff9f0e1</uuid>
  <memory unit='KiB'>262144</memory>
  <currentMemory unit='KiB'>262144</currentMemory>
  <vcpu placement='static'>1</vcpu>
  <os>
    <type arch='ppc' machine='ppce500'>hvm</type>
    <kernel>/boot/uImage</kernel>
    <initrd>/home/root/my.rootfs.ext2.gz</initrd>
    <cmdline>root=/dev/ram rw console=ttyS0,115200</cmdline>
  </os>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-ppc</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
    <memballoon model='virtio'/>
  </devices>
</domain>
```

3. Now the domain can be defined:

```
# virsh define kvm1.xml
Domain kvm1 defined from kvm1.xml

# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm1                           shut off
```

4. Next start the domain. This starts the VM and boots the guest Linux.

```
# virsh start kvm1
Domain kvm1 started
```

```
# virsh list
 Id    Name                           State
----------------------------------------------------
 3     kvm1                           running
```

5. The virsh console command can be used to connect to the console of the running Linux domain.

```
# virsh console kvm1
Connected to domain kvm1
Escape character is ^]

Poky 9.0 (Yocto Project 1.4 Reference Distro) 1.4 model : qemu ppce500 ttyS0

model : qemu ppce500 login:
```

Press CTRL +] to exit the console.

6. To stop the domain use the destroy command:

```
# virsh destroy kvm1
Domain kvm1 destroyed

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm1                           shut off
```

7. To remove the domain from libvirt, use the undefine command:

```
# virsh undefine kvm1
Domain kvm1 has been undefined

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
```

11.2.5.6.9 Libvirt KVM/QEMU -- Adding Devices Example (Power Architecture)

This example shows how devices (virtual network, USB, and PCI) can be added to a libvirt domain. The steps are identical to the simple domain example shown in Libvirt KVM/QEMU Example (Power Architecture) on page 2367 , (except some additional preparation is needed for step #1):

1. Create a text file containing the QEMU command line
2. Use **virsh domxml-from-native** to create the libvirt XML
3. Use **virsh define** to define the QEMU domain
4. Use **virsh start** to start the domain

When defining the QEMU command line options in step #1 to add the network, USB, and PCI devices it is necessary to explicitly specify the PCI slot number for each device (all the devices in this example appear on the VM's virtual PCI bus). The remainder of this example explains how to do this.

The normal QEMU command line arguments to assign these devices to a virtual machine would look something like:

- for a virtual network interface

```
-netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -
device virtio-net-pci,netdev=tap0
```

- for the passthrough of USB device on bus #2, port #1

```
-device usb-ehci,id=ehci -device usb-host,bus=ehci.0,hostbus=2,hostport=1
```

- for the passthrough of PCI device 0000:01:00.0

```
-device vfio-pci,host=0000:01:00.0
```

(For further information on these command line argument, please refere to the KVM/QEMU documentation)

All these devices will appear on the virtual PCI bus in the virtual machine. However, in the context of libvirt it is necessary to explicitly assign the PCI slot for each device and therefore it is necessary to determine what slot are occupied and free.

First, start the virtual machine with libvirt **without the new devices** so that the default PCI slot assignment can be viewed (the example is for a domain called "kvm1" on a p4080ds):

```
$ echo '/usr/bin/qemu-system-ppc -m 512 -nographic -M ppce500 -kernel /home/root/uImage -initrd /
home/root/fsl-image-minimal-p4080ds.rootfs.ext2.gz  -append "root=/dev/ram rw
console=ttyS0,115200" -enable-kvm -smp 8 -mem-path /var/lib/hugetlbfs/pagesize-16MB -name kvm1 -
serial pty' > kvm1.args

$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$ virsh define kvm1.xml
$ virsh start kvm1
```

Next, view the devices on the PCI bus:

```
$ virsh qemu-monitor-command --hmp kvm1 'info pci'
  Bus  0, device   0, function 0:
    PCI bridge: PCI device 1957:0030
      BUS 0.
      secondary bus 0.
      subordinate bus 0.
      IO range [0x0000, 0x0fff]
      memory range [0x00000000, 0x000fffff]
      prefetchable memory range [0x00000000, 0x000fffff]
      BAR0: 32 bit memory at 0xc0000000 [0xc00fffff].
      id ""
  Bus  0, device   1, function 2:
    USB controller: PCI device 8086:7020
      IRQ 0.
      BAR4: I/O at 0xffffffffffffffff [0x001e].
      id "usb"
  Bus  0, device   3, function 0:
    Class 0255: PCI device 1af4:1002
      IRQ 0.
      BAR0: I/O at 0x1000 [0x101f].
      id "balloon0"
```

In this example it can be seen that the highest occupied slot is 0x3, which means that slots 0x4 and higher are available.

The explicit definition of the PCI slot numbers on the QEMU command line looks like this:

- for a virtual network interface (PCI slot/addr 0x4)

```
-netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -
device virtio-net-pci,netdev=tap0,bus=pci.0,addr=0x4
```

- for the passthrough of USB device on bus #2, port #1 (PCI slot/addr 0x5)

```
-device usb-ehci,id=ehci,bus=pci.0,addr=0x5 -device usb-host,bus=ehci.0,hostbus=2,hostport=1
```

- for the passthrough of PCI device 0000:01:00.0 (PCI slot/addr 0x6)

```
-device vfio-pci,host=0000:01:00.0,bus=pci.0,addr=0x06
```

The virtual machine's PCI bus is "pci.0".

The complete command sequence to define the domain and start it looks like:

```
$ echo '/usr/bin/qemu-system-ppc -m 512 -nographic -M ppce500 -kernel /home/root/uImage -initrd /
home/root/fsl-image-minimal-p4080ds.rootfs.ext2.gz  -append "root=/dev/ram rw
console=ttyS0,115200" -enable-kvm -smp 8 -mem-path /var/lib/hugetlbfs/pagesize-16MB -name kvm1 -
serial pty -netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-
ifdown,vhost=on -device virtio-net-pci,netdev=tap0,bus=pci.0,addr=0x4 -device usb-
ehci,id=ehci,bus=pci.0,addr=0x5 -device usb-host,bus=ehci.0,hostbus=2,hostport=1 -device vfio-
pci,host=0000:01:00.0,bus=pci.0,addr=0x06' > kvm1.args

$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$ virsh define kvm1.xml
$ virsh start kvm1
```

Libvirt also supports adding devices into a domain by modifying the domain XML file directly.

Shutdown the guest domain and edit the guest XML definition with the virsh edit command

```
$ virsh edit kvm1
```

- for a virtual network interface (PCI slot/addr 0x4)

```
<interface type="ethernet">
  <script path="/home/root/qemu-ifup"/>
  <model type="virtio"/>
  <driver name="vhost"/>
  <address type='pci' domain='0x0000' bus='0x00' slot='0x04' function='0x0'/>
</interface>
```

- for the passthrough of PCI device 0000:01:00.0 (PCI slot/addr 0x6)

```
<hostdev mode="subsystem" type="pci" managed="yes">
  <driver name="vfio"/>
  <source>
    <address domain="0x0000" bus="0x01" slot="0x06" function="0x0"/>
  </source>
</hostdev>
```

Start the domain again.

It is also possible to add and remove devices by defining the devicde in a standalone XML file. The **virsh attach-device/ detach-device** commands commands can be used when the domain is not active.

For example,

```
$ cat vhost_on.xml
<interface type='ethernet'>
  <script path='/home/root/qemu-ifup'/>
  <model type='virtio'/>
  <driver name='vhost'/>
  <address type='pci' domain='0x0000' bus='0x00' slot='0x04' function='0x0'/>
</interface>
```

Attach device to the guest domain using **virsh attach-device.** The resulting XML file can be dumped to find the added device:

```
$ virsh attach-device --config kvm1 vhost_on.xml
$ virsh dumpxml kvm1
```

11.2.6 KVM for ARM Architecture Users Guide and Reference

11.2.6.1 Introduction to KVM and QEMU

11.2.6.1.1 Overview

This document is a guide and tutorial to building and using KVM (Kernel-based Virtual Machine) on NXP QorIQ SoCs.

Virtualization provides an environment that enables running multiple operating systems on a single computer system. Virtualization uses hardware and software technologies together to enable this by providing an abstraction layer between system hardware and the OS. The isolated environment in which OSes run is known as a *virtual machine* (or VM). The abstraction layer that manages all this is referred to as a *hypervisor or virtual machine manager*. The hypervisor layer operates at a privilege level higher than that of the operating systems, thus enabling it to enforce system security, ensure that virtual machines cannot interfere with each other, and transparently provide other services such as I/O sharing to the VM.

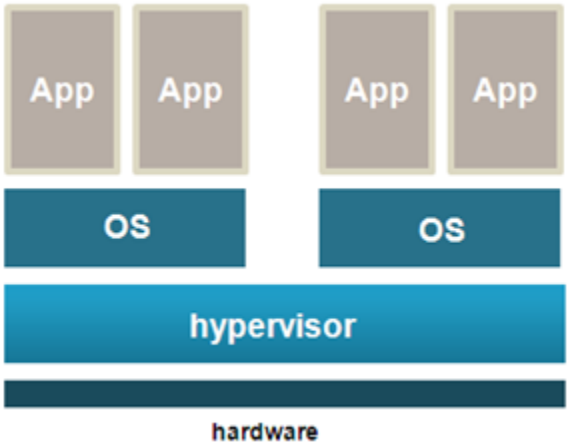

Figure 373.

KVM is a Linux kernel driver that together with QEMU, an open source machine emulator, provides an open source virtualization platfiorm based on Linux. KVM and QEMU together act as a virtual machine manager that can boot and run operating systems in virtual machines. See Figure below.

In this document the term *host* kernel refers to the underlying instance of Linux with the KVM driver that acts as the hypervisor. The term *guest* refers to the operating system, such as Linux, that runs in a virtual machine. A virtual machine will be referred to as a "VM".

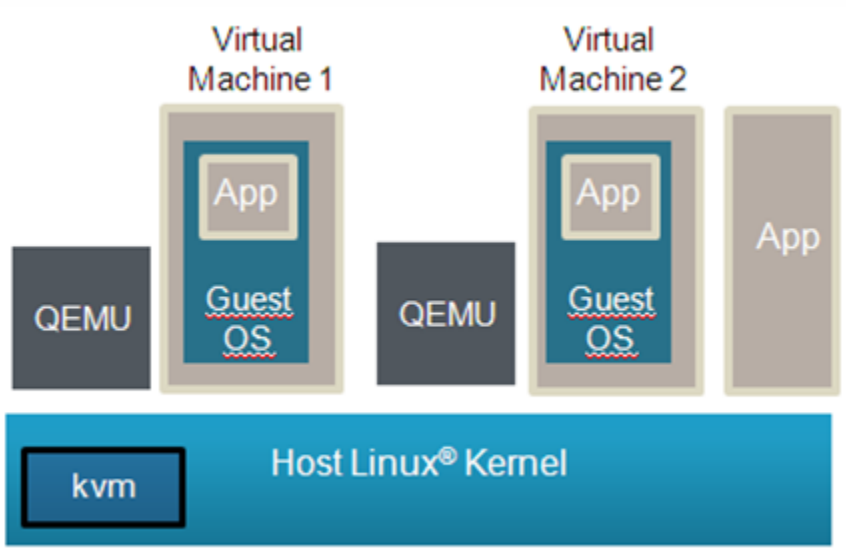

Figure 374.

NXP QorIQ SoCs based on ARM v7 and ARM v8 CPUs are supported.

11.2.6.1.2 Organization of this Document

This document is organized as follows:

- Introduction to KVM and QEMU on page 2372 provides an introduction to KVM/QEMU, including overview information and references.
- Building QEMU and KVM on page 2376 provides information on how to build QEMU and the Linux kernel with KVM.
- Using QEMU and KVM on page 2382 describes how to use KVM/QEMU, including how to invoke QEMU to start virtual machines and how to set up virtual I/O and passthrough I/O devices.
- Virtual machine reference on page 2387 provides a reference for virtual machines-- details about initial VM state, virtual CPUs, and virtual I/O devices. This information is relevant when porting an OS or device driver to a KVM-based virtual machine.
- Debugging virtual machines on page 2390 describes facilities available for debugging software running in a virtual machine.
- KVM/QEMU How-to's on page 2392 provides a set of examples for common tasks.

11.2.6.1.3 Virtual Machine Overview

A guest OS running in a KVM/QEMU virtual machine "sees" a hardware environment similar to running on a physical board. The guest sees CPUs, memory, and a number of I/O devices. Some aspects of this environment are virtualized (emulated in software by KVM/QEMU) but this virtualization is mostly transparent to the guest, and changes to the guest are typically not required to run in a virtual machine.

The number of virtual machines that can be run simultaneously is only limited by the amount of available resources (like any other application on Linux).

KVM/QEMU implements a generic virt machine which is described completely by the device tree. The virtual machine contains the following resources:

- one or more ARMv7/ARMv8 virtual CPUs
- memory

- virtual console based on an emulated PL011
- virtio over PCI (used for virtual devices such as block and network devices)
- ARM Virtual Generic Interrupt Controller
- ARM virtual timer and counter

11.2.6.1.4 Introduction to KVM and QEMU

QEMU (pronounced KYOO-em-yoo) is a software-based machine emulator that emulates a variety of CPUs and hardware systems. KVM is a Linux kernel device driver that provides virtual CPU services to QEMU. The two software components work together as a virtual machine manager.

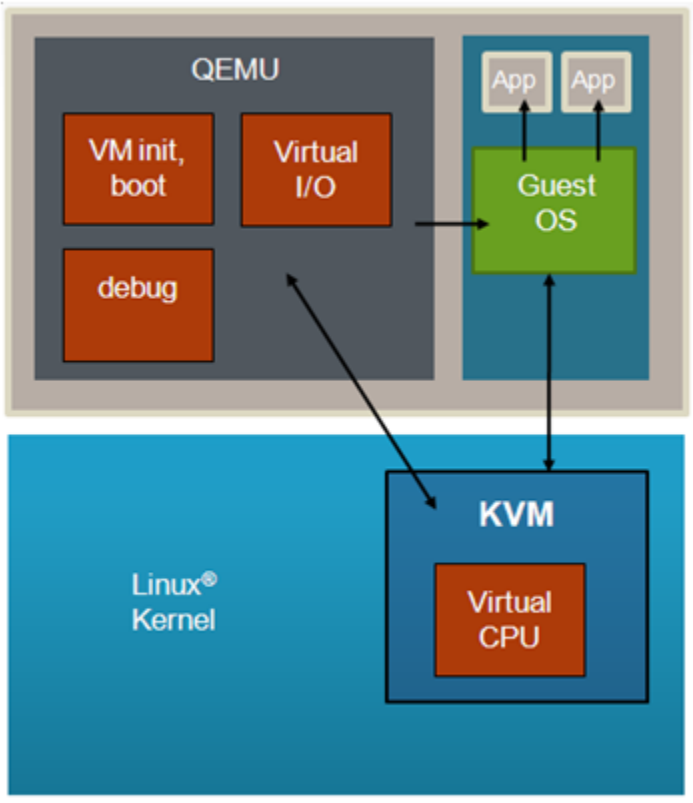

Figure 375.

QEMU is a Linux user-space application that runs on the host Linux instance and is used to start and manage a virtual machine. QEMU provides the following:

- A command line interface that provides extensive customization and configuration of a virtual machine when it is started-- e.g. type of VM, which images to load, and how virtual devices are configured
- Loading of all images needed by the guest-- e.g kernel images, root filesystem, guest device tree
- Setting the initial state of the VM and booting the guest
- Virtual I/O services, such as virtual network interfaces and virtual disks
- Debug services-which provide the capability to debug a guest OS using GDB (similar to a virtual JTAG)

KVM is a device driver in the Linux kernel whose key role in the VM architecture is to provide virtual CPU services. These services involve two aspects:

1. First, KVM provides an API set that QEMU uses to set and get the state of virtual CPUs and run them. For example, QEMU sets the initial values of the CPU's registers before starting the VM.
2. Second, after KVM starts a guest OS, certain operations (such as privileged instructions) performed by the OS cause an exception (or exit) into the host Linux kernel that must be handled and processed by KVM. This handling of traps is referred to as "emulation". These traps are transparent to the guest.

The KVM API is documented in the Linux kernel-- Documentation/virtual/kvm/api.txt.

KVM/QEMU supports virtual I/O which allows sharing of physical I/O devices by multiple VMs. Virtual network and block I/O are supported. See For More Information on page 2376 for references that provide additional information on virtio.

11.2.6.1.5 Device Tree Overview

A device tree is a data structure that describes hardware resources such as CPUs, memory, and I/O devices. An device tree aware OS is passed a device tree which it reads to determine what hardware resources are available.

The host Linux kernel is booted first, typically by u-boot (an open source bootloader). U-boot passes the kernel a **hardware** device tree that lists and describes all system hardware resources available to the host kernel (CPUs/cores, memory, interrupt controller and I/O).

Similarly, when a guest OS is booted in a KVM/QEMU virtual machine, QEMU passes it a **guest** device tree that describes all the hardware resources in the VM. See Figure below.

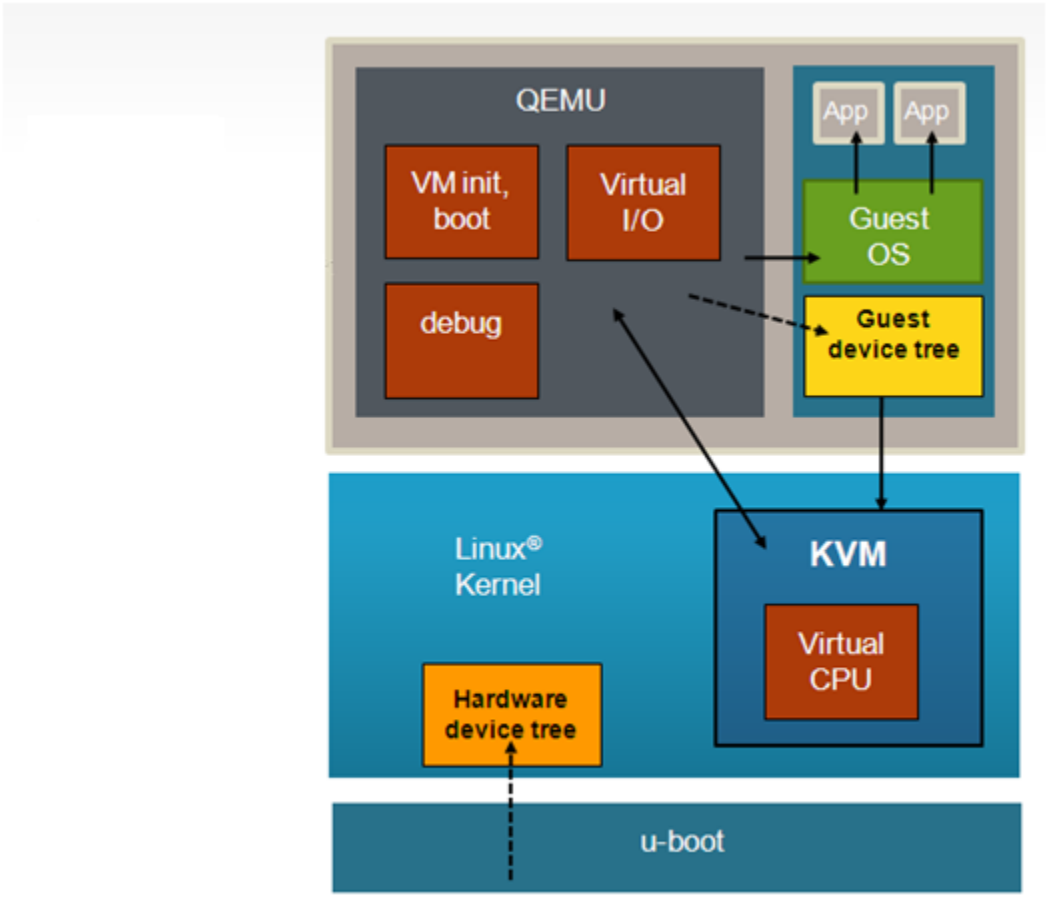

Figure 376.

The guest device tree is generated by QEMU and is used to define the resources a virtual machine will see. The guest device tree defines CPUs, memory, and I/O devices. QEMU places the guest device tree in the virtual machine's memory prior to starting the virtual machine.

11.2.6.2 Building QEMU and KVM

11.2.6.2.1 Overview

Linux with KVM enabled and QEMU can be built as part of the standard build process used to build the NXP SDK using Yocto.

They can also be built in a standalone manner outside of Yocto.

The build instructions in the sections that follow assume a working understanding of how to use Yocto to build the NXP SDK. Please refer to the Yocto documentation in the SDK.

11.2.6.2.2 Building Linux with KVM

11.2.6.2.2.1 Overview

KVM is a component in the Linux kernel. KVM is not enabled in the default kernel configuration in the NXP SDK and KVM features must be enabled using the kernel's menuconfig configuration utility prior to building the kernel.

In the sections that follow configuration options are described for both the host and guest Linux kernel. The host and guest kernels can be built separately, but it is possible to build a single Linux kernel image that can be used for both the host and the guest.

The kernel configuration options described below would be the same if building the kernel standalone (outside of Yocto).

The following sections provide high level build information:

- Running menuconfig with Yocto - describes how to configure the kernel under Yocto
- Quick Start - Recommended Configuration Options - in a single step shows all the recommended configuration options to enable to build a kernel with virtual I/O enabled with the same kernel image serving as both host and guest.

The following sections provide more detailed information on each KVM-related configuration option for host and guest:

- Host Kernel: Enabling KVM - describes the configuration options to enable KVM in the host kernel.
- Host Kernel: Enabling Virtual Networking - describes how to enable bridging and tun/tap in the host kernel which enables virtual networking.
- Guest Kernel: Enabling Network and Block Virtual I/O - describes how to enable virtual I/O in the guest kernel.
- Guest kernel: Enabling console - describes how to enable the console for the guest kernel

11.2.6.2.2.2 Running menuconfig with Yocto

The prerequisite and starting point for building the Linux kernel with KVM enabled is performing a standard kernel build with Yocto.

```
$ bitbake virtual/kernel
```

To change the kernel configuration options use the Linux standard menuconfig utility. To invoke menuconfig under Yocto do the following from the Yocto build environment:

```
$ bitbake -c menuconfig virtual/kernel
```

Note: Depending on what build steps may have been done previously, it may be necessary to invoke the command 'bitbake -c clean virtual/kernel' prior to running the menuconfig command.

The result will be an xterm that appears that displays the menuconfig screen:

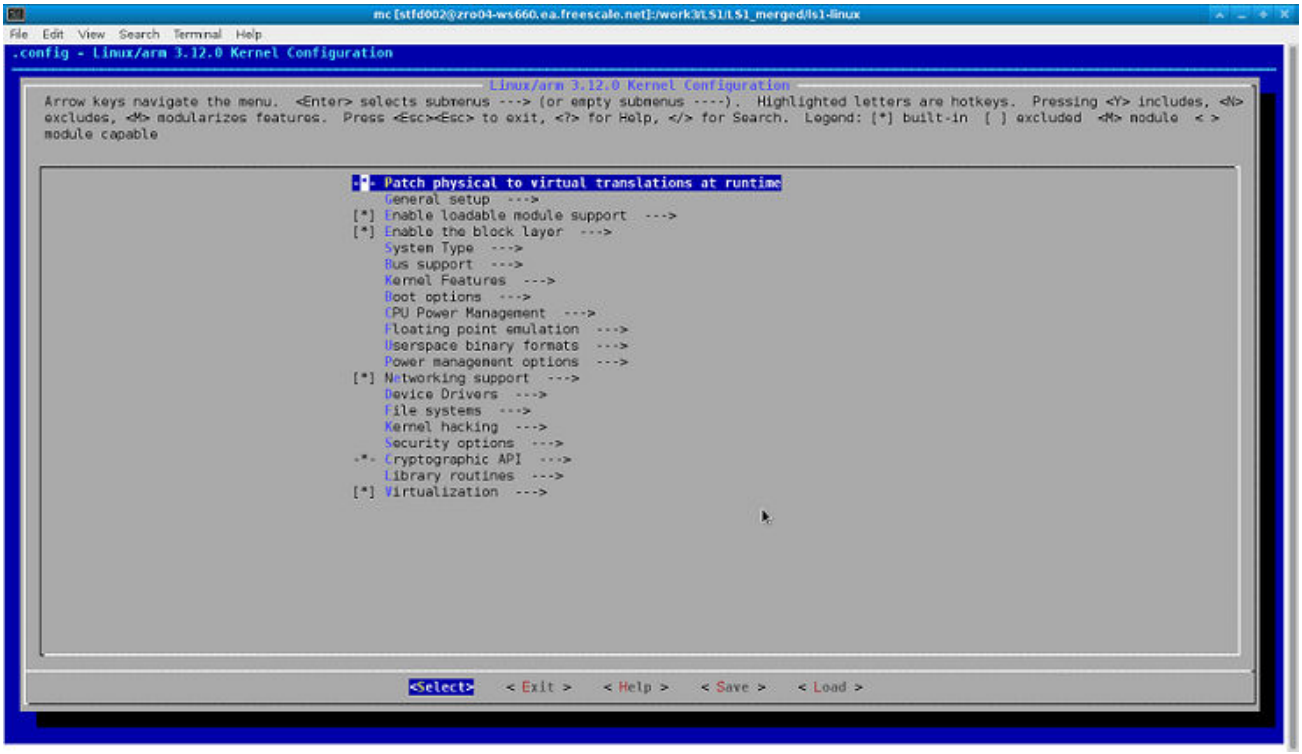

Figure 377.

11.2.6.2.2.3 Quick Start - Recommended Configuration Options

The steps below show all the recommended configuration options to enable to build a kernel with virtual I/O enabled with the same kernel image serving as both host and guest. The sections that follow explain these options in further detail.

Note: The configuration options are enabled by default in the kernel configuration. However, they are are listed here for reference.

1. From the main menuconfig window enable virtualization:

```
[*] Virtualization
```

2. In the virtualization menu enable the following options:

```
[*] Kernel-based Virtual Machine (KVM) support
```

3. Enable network bridging

```
Networking support  --->
    Networking options  --->
        <*> 802.1d Ethernet Bridging
```

4. Enable virtio PCI

```
Device Drivers  --->
    Virtio drivers  --->
      <*> PCI driver for virtio devices
```

5. Enable virtio for block devices

```
Device Drivers  --->
    [*] Block devices  --->
        <*>   Virtio block driver
```

6. Enable virtio for network devices

```
[*] Network core driver support
        <*>   Universal TUN/TAP device driver support
        <*>   Virtio network driver
```

7. Enable vhost for virtio network devices

```
[*] Virtualization
    <*>   Host kernel accelerator for virtio net
```

8. Enable Huge TLB file support

```
File Systems --->
    Pseudo filesystems --->
        [*] Huge TLB file system support
```

9. Enable guest serial support

```
Device Drivers --->
    Character devices --->
        Serial drivers --->
             <*> ARM AMBA PL011 serial port support
             [*]   Support for console on AMBA serial port
```

11.2.6.2.2.4 Host Kernel: Enabling KVM

This section describes the core, basic options needed to enable KVM in the host kernel. KVM is enabled in the host kernel under the virtualization menu of the main kernel menuconfig window.

```
[*] Virtualization
```

Core KVM support is enabled as follows:

```
[*] Kernel-based Virtual Machine (KVM) support
```

11.2.6.2.2.5 Host Kernel: Enabling Virtual Networking

Virtual network interfaces on page 2384 describes how virtual networking can be used to give each VMs a virtual network interface which share physical network interfaces in Linux.

One common approach to configuring virtual networking is for QEMU to use a tun/tap interface bridged to a physical network interface. To do this Ethernet bridging and the kernel's tun/tap features must be enabled in the host kernel:

```
Networking support  --->
          Networking options  --->
                    <*> 802.1d Ethernet Bridging
```

```
Device Drivers  --->
          [*] Network core driver support
                    <*>   Universal TUN/TAP device driver support
```

In order to enable vhost-net, the following config option should ne enabled:

```
[*] Virtualization
    <*>   Host kernel accelerator for virtio net
```

11.2.6.2.2.6 Guest Kernel: Enabling Network and Block Virtual I/O

Virtio is a framework for doing paravirtualized I/O using QEMU/KVM. In order to support communication between guest and hypervisor virtio uses a PCI transport protocol.

Below the kernel configuration options are shown to enable virtio-pci:

```
Device Drivers  --->
    Virtio drivers  --->
      <*> PCI driver for virtio devices
```

Below the kernel configuration options are shown to enable virtio drivers in the Linux kernel to support networking I/O and block (disk) I/O.

```
Device Drivers  --->
          [*] Network device support  --->
                    <*>   Virtio network driver
Device Drivers  --->
          [*] Block devices  --->
                    <*>   Virtio block driver
```

11.2.6.2.2.7 Guest kernel: Enabling console

QEMU emulates an AMBA/PL011 console.

Below the kernel configuration options are shown to enable console:

```
Device Drivers --->
    Character devices --->
        Serial drivers --->
             <*> ARM AMBA PL011 serial port support
             [*]   Support for console on AMBA serial port
```

11.2.6.2.3 Building QEMU

QEMU is a standard package in the QorIQ SDK and will be built for the following Yocto build configurations:

- fsl-image-virt
- fsl-image-full

To add QEMU to another Yocto build configuration, edit the conf/local.conf file and add the IMAGE_INSTALL_append variable:

```
IMAGE_INSTALL_append = " qemu"
```

After a Yocto build is complete, the target root filesystem will contain the following QEMU components that are required for using KVM/QEMU:

```
/usr/bin/qemu-system-arm                # QEMU executable for ARMv7 platforms
/usr/bin/qemu-system-aarch64            # QEMU executable for ARMv8 platforms
```

QEMU can be built as an individual component in the Yocto environment as well, it's package name is "qemu".

To clean and rebuild QEMU from the Yocto build environment:

```
$ bitbake -c clean qemu
$ bitbake qemu
```

11.2.6.2.4 Creating a host Linux root filesystem

11.2.6.2.4.1 Overview

Creating a Linux root filesystem is out of the scope of this document. Please reference the NXP QorIQ SDK for more information on how to create root filesystems with Yocto. This section describes the software components needed on a root filesystem to use KVM/QEMU.

The host root filesystem is the filesystem booted by the host kernel. The host rootfs is distinct from a guest root filesystem which may be needed by certain guest such as Linux.

A host root filesystem capable of running Linux as a guest needs the following components:

- Guest Linux kernel image (Image or zImage). *Note:*Only zImage is supported for ARMv7 platforms.
- QEMU executable
- Guest root filesystem
- Dynamic libraries needed by QEMU (libfdt, libz, glib2.0). These libraries are standard components in a Yocto-created rootfs.

Example host root filesystem layout with the required components to boot a Linux guest (excluding shared libraries):

```
/root/zImage                            # guest Linux kernel
/root/rootfs.ext2.gz                    # guest rootfs
/usr/bin/qemu-system-arm                # QEMU for ARMv7 platforms
/usr/bin/qemu-system-aarch64            # QEMU for ARMv8 platforms
```

11.2.6.2.4.2 Adding Images to a Root Filesystem with Yocto

If using Yocto, as described in Building QEMU on page 2380, the root filesystem produced by the build process will contain QEMU and the example guest device trees provided by the SDK.

A feature is also available with Yocto and the SDK to add arbitrary additional images to the root filesystem. This is done using the merge-files component in Yocto.

Any files and directories copied to the "merge" directory (see path below) will be copied to the root filesystem created by Yocto:

```
meta-freescale/recipes-extended/merge-files/merge-files/merge
```

After populating the merge directory with the desired files, clean and rebuild the rootfs. See example below for the fsl-image-core image type:

```
$ bitbake -c install -f merge-files
$ bitbake merge-files
$ bitbake fsl-image-core
```

See the how-to article Quick-start Steps to Build and Deploy KVM Using Yocto on page 2392 for a more detailed example.

11.2.6.3 Using QEMU and KVM

11.2.6.3.1 Overview of Using QEMU

QEMU is used to start virtual machines and is built and included in the rootfs created by Yocto. The QEMU application is named **qemu-system-arm** (for 32 bit platforms) or **qemu-system-aarch64** (for 64 bit platforms).

In addition to the QEMU executable itself, the following is a list of the minimum components that must be available on the target system to launch a virtual machine using QEMU:

- The host Linux kernel on the target must be built with virtualization support for KVM enabled as described in Building Linux with KVM on page 2376.
- A guest OS kernel image (e.g. zImage or Image for Linux)
- A guest root filesystem (If needed by the guest OS. For example, a Linux guest requires a rootfs.)
- Recommended: A working network interface (to interface to the guest's console and the QEMU monitor)

See the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2394 for an example of how to boot a virtual machine with a rootfs created by Yocto.

The QEMU Emulator User Documentation [1] (see References on page 2376) contains complete documentation for all QEMU command line arguments. The Table below summarizes some of the flags and arguments for basic operation.

Table 591.

Argument	Descriptions
-enable-kvm	Specifies that the Linux KVM should be used for the virtual machine's CPUs
-nographic	Disables graphical output-console will be on emulated serial port.
-M *machine*	Specifies the type of virtual machine. One value is supported: • virt
-smp *cpu_count*	Specifies the number of CPUs for the virtual machine. The number of virtual CPUs allowed is the same as the value of the CONFIG_NR_CPUS config option in the host Linux kernel. To see this value issue the following command from Linux on the target board: `zcat /proc/config.gz | grep NR_CPUS`
-kernel *file*	Specifies the guest OS image. The supported image types are in *Image* format (the generic Linux kernel binary image file) and *zImage* (a compressed version of the Linux kernel image)

Table continues on the next page...

Table 591. (continued)

Argument	Descriptions
-initrd *file*	Specifies a root filesystem image
-append *cmdline*	Use *cmdline* as the guest OS kernel command line (passed in the bootargs property of the /chosen node in the guest device tree)
-serial *dev*	Redirects the virtual serial port to the host device *dev*. QEMU supports many possible host devices. Please refer to the QEMU User Documentation [1] (see References on page 2376) for complete details. Note: if using a tcp device with the **server** option QEMU will wait for a connection to the device before continuing unless the **nowait** option is used.
-m *megs*	Specifies the size of the VM's RAM in megabytes. This option is ignored if using direct mapped memory. See Virtual Machine Memory on page 2384 for further details on options for allocating memory.
-mem-path *path*	Specifies the path to a file from which to allocate memory for the virtual machine. This option should be used to allocate memory from hugetlbfs. See Virtual Machine Memory on page 2384 for further details on options for allocating memory.
-monitor *dev*	Redirects the QEMU monitor to the host device *dev*. QEMU supports many possible host devices. Please refer to the QEMU User Documentation [1] (see References on page 2376) for complete details. Note: if using a tcp device with the **server** option QEMU will wait for a connection to the device before continuing unless the **nowait** option is used.
-S	Do not start CPU at startup (you must type 'c' in the monitor). This can be useful if debugging.
-gdb *dev*	Wait for gdb connection on device dev
-drive *[args]*	Used to create a virtual disk in a virtual machine. See Virtual block devices on page 2385 for additional information.
-netdev *[args]* -device virtio-net-device *[args]*	The -netdev and -device virtio-net-device arguments specify the network backend and front end for createing virtual network devices in virtual machines. See Virtual network interfaces on page 2384 for additional information.
-cpu *model*	Select CPU model. Only one model is supported: • host

Below is an example command line a user would run from the host Linux to start virt virtual machine booting a Linux guest:

ARMv7:

```
qemu-system-arm -enable-kvm -m 512 -nographic -cpu host -machine type=virt -kernel /boot/zImage -
serial tcp::4446,server,telnet -initrd /boot/guest.rootfs.ext2.gz -append 'root=/dev/ram0 rw
console=ttyAMA0 rootwait earlyprintk' -monitor stdio
```

ARMv8:

```
qemu-system-aarch64 -enable-kvm -m 512 -nographic -cpu host -machine type=virt -kernel /boot/Image
-serial tcp::4446,server,telnet -initrd /boot/guest.rootfs.ext2.gz -append 'root=/dev/ram0 rw
console=ttyAMA0 rootwait earlyprintk' -monitor stdio
```

11.2.6.3.2 Virtual Machine Memory

QEMU allocates and loads images into a VM's memory prior to starting the VM. The amount of memory needed for a virtual machine will be dependent on the workload to be run in the VM. There are two ways to allocate memory:

1. Allocation via hugetlbfs

   Hugetlbfs is a Linux mechanism that allows applications to allocate memory backed large physically contiguous regions of memory. QEMU can take advantage of hugetlbfs for allocation of memory for virtual machines, which can provide a significant performance improvement over malloc allocated memory. Hugetlbfs allocated memory provides the flexibility of memory that can be allocated and freed with performance comparable to direct mapped memory.

   The 32 bit ARMv7 implementation in Linux supports 2MB sized huge pages. The 64 bit ARMv8 implementation in Linux supports 2MB and 1GB sized huge pages (for 4K granularity page size).

   The **-mem-path** argument to QEMU specifies the path to the hugetlbfs mount point where the huge pages should be allocated from.

   The **-m** argument to QEMU specifies the amount of memory to allocate to the virtual machine. There are no constraints on the size passed to this argument other than that the amount of memory must fit within the constraints of the system and be enough for the workload in the VM.

   See the how-to article Quick-start Steps to Run KVM Using Hugetlbfs on page 2394 for an example of how to use hugetlbfs.

2. Allocation via malloc

   The default for QEMU is to allocate guest memory by the standard malloc facility available to user space applications in Linux. The amount of memory is specified with the -m command line argument. Malloc'ed memory has the flexibility of being allocated and freed by QEMU as needed. However, malloc'ed memory is backed by 4KB physical pages that are not contiguous and emulation is required by KVM to present a contiguous guest physical memory region to the VM. This approach is discouraged since the emulation can result in a substantial performance penalty for certain workloads.

The guest device tree generated by QEMU will contain a memory node that specifies the total amount of memory.

NOTE

A virtual machine's memory is part of the address space of the QEMU process. This means that the amount of memory allocated to a VM is limited by the standard limits that exist for Linux processes. A 32-bit host kernel has a 2GiB virtual address space used for stack, text, and other data, and this limits the amount of memory that can be allocated to a VM.

11.2.6.3.3 Virtual network interfaces

QEMU provides a number of options for creating virtual network interfaces in virtual machines. Virtual network interfaces are specified using the QEMU command line and guest software sees them as memory mapped devices.

There are two aspects of virtual network interfaces with QEMU:

1. The network “front-end”, which is the network card as seen by the guest. This is specified with the **-device** QEMU argument. The argument to specify a virtio network front end would look like: **-device virtio-net-pci**
2. The network "backend", which connects the network card to some network. Network backend options include user mode networking, a host TAP interface, sockets, or virtual distributed Ethernet. The network backend is specified using the **-netdev** command line argument of QEMU. Note: It is possible to connect two virtual machines using virtual network interfaces. Normally QEMU userspace process emulates I/O accesses from the guest. However, there is an in-kernel implementation: *vhost-net* which puts the data plane emulation code into the kernel.

For example, to use a virtio NIC card with a TAP interface back-end the QEMU command line argument would look like:

```
-netdev tap,id=tap0,script=/root/qemu-ifup -device virtio-net-pci,netdev=tap0
```

The script “/root/qemu-ifup” is a script that QEMU invokes and passes the TAP interface name as an argument. For example, the script could add the TAP interface to an Ethernet bridge.

See the QEMU Users Manual [1] (see References on page 2376) for detailed information about command line options and the types of network interfaces and backends. For best performance, the virtio front-end is recommended.

For additional information about QEMU networking see the references in For More Information on page 2376.

For a detailed example, see the how-to article How to Use Virtual Network Interfaces Using Virtio on page 2396 .

11.2.6.3.4 Virtual block devices

There are a number of approaches to provide a virtual disk to a KVM/QEMU virtual machine. A guest disk image can be a single raw file on the host filesystem, a file in a virtual disk format such as qcow2 and vdi, or a block device on the host Linux system. The virtual disk is assigned on the QEMU command line. In the example below, the file **my_guest_disk** is a disk image and is assigned to the VM when QEMU is launched:

```
-drive file=my_guest_disk,cache=none,if=virtio
```

Refer to the QEMU Users manual [1] (see References on page 2376) for details on the types of virtual disk images that may be created and the related arguments to QEMU.

For a detailed example, see the how to article How to Use Virtual Disks Using Virtio on page 2398.

11.2.6.3.5 Using KVM/QEMU with libvirt

Libvirt is an open source toolkit that enables the management of Linux-based virtualization technologies such as KVM/QEMU virtual machines and Linux containers.

See the chapter ***Libvirt Users Guide*** (section under Linux User Space) for an overview of libvirt and its capabilties, features, and basic usage information.

The libvirt users guide describes the lifecycle of a virtual machine being managed by libvirt. To manage a KVM/QEMU virtual machine as a libvirt domain, it is first defined in an XML file and then a "define" operation (such as **virsh define**) is used to make libvirt aware of the domain. The domain can then be started, which causes QEMU to be invoked to boot the virtual machine. Libvirt tools can then be used to manage the running domain.

Libvirt URIs

To manage KVM/QEMU domains in libvirt, a QEMU URI is used:

- For a local node: *qemu:///system*
- For a remote node: *qemu[+transport]:///[hostname]/system*

See the libvirt users guide for more information on URIs.

Creating a KVM/QEMU Domain

The recommended procedure for creating a KVM/QEMU domain is to:

1. Identify the QEMU command line that fully specifies the desired capabilities and image to boot the virtual machine. Place the command line in a text file, including the full path to the QEMU executable and any images.
2. Convert the QEMU command line to libvirt XML with the *virsh domxml-from-native* command.
3. Use *virsh define* and *virsh start* to define and start the domain.

See Libvirt KVM/QEMU Example (ARM Architecture) on page 2403 for an example of creating and managing a KVM/QEMU domain.

Managing libvirt Domains

See the libvirt users guide for more information on URIs.

A running domain can then be managed by virsh (or other libvirt compatible development tools). Below are some examples of supported management operations:

- *virsh console* - connects to the console of the VM
- *virsh suspend* - suspends a running VM. After *suspend* the domain is in the "paused" state.
- *virsh resume* - resumes a suspended domain. After *resume* the domain is in the "running" state
- *virsh list* - lists active and running VMs
- *virsh reset* - resets the VM
- *qemu-monitor-command* - allows interactions with a VMs QEMU monitor

Libvirt XML

As described above the *virsh domxml-from-native* command is used to convert a QEMU command line into a libvirt XML file.

The full definition of the XML format and all XML tags is specified at: http://libvirt.org/formatdomain.html

11.2.6.3.6 VMs and the Linux Scheduler

Each virtual machine appears to the host Linux as a process with each virtual CPU in the VM implemented as a thread. A VM appears as an instance of QEMU when looking at Linux processes as can be seen in the example below:

```
$ ps -ef
                o
                o
root      1333     1  0 Oct01 ttyS0 00:00:00       -sh
root      1336     2  0 08:24 ?        00:00:00    [kworker/u4:2]
root      1372  1333 18 08:27 ttyS0    00:00:17    qemu-system-arm   -enable-kvm -m
root      1361  1304  0 08:28 ?        00:00:00    sshd: root@pts/0
root      1363  1361  0 08:28 pts/0    00:00:00    -sh
                o
                o
```

CPUs appear as threads. To see thread IDs use the `info cpus` command in the QEMU monitor. Example of a VM with 8 virtual CPUs:

```
(qemu) info cpus
* CPU #0: thread_id=1984
  CPU #1: (halted) thread_id=1985
  CPU #2: (halted) thread_id=1986
  CPU #3: (halted) thread_id=1987
  CPU #4: (halted) thread_id=1988
  CPU #5: (halted) thread_id=1989
```

```
  CPU #6: (halted) thread_id=1990
  CPU #7: (halted) thread_id=1991
```

To see the QEMU threads using the ps command:

```
root@ls_machine:~# ps -eL | grep qemu
 1981  1981 ttyS1    00:00:00 qemu-system-aar
 1981  1982 ttyS1    00:00:00 qemu-system-aar
 1981  1983 ttyS1    00:00:00 qemu-system-aar
 1981  1984 ttyS1    00:00:00 qemu-system-aar
 1981  1985 ttyS1    00:00:00 qemu-system-aar
 1981  1986 ttyS1    00:00:00 qemu-system-aar
 1981  1987 ttyS1    00:00:00 qemu-system-aar
 1981  1988 ttyS1    00:00:00 qemu-system-aar
 1981  1989 ttyS1    00:00:00 qemu-system-aar
 1981  1990 ttyS1    00:00:00 qemu-system-aar
 1981  1991 ttyS1    00:00:00 qemu-system-aar
```

Being a Linux thread means that standard Linux mechanisms can be used to control aspects of how the threads are scheduled relative to other threads/processes. These mechanisms include:

- process priority
- CPU affinity
- isolcpus
- cgroups

11.2.6.4 Virtual machine reference

11.2.6.4.1 VM Overview

In general the architecture of KVM/QEMU is such that few changes should be needed to guest software to run in a VM-- i.e. a full virtualization approach is used, which means that virtual CPUs and virtual I/O devices behave like the physical hardware they are emulating.

However, there are some differences between virtual machines and native hardware that should be considered when targeting an OS to a KVM virtual machine. These differences can be divided into 2 general categories that will be discussed in further detail in this section:

1. Initial state and boot
2. CPUs

11.2.6.4.2 Memory Map of Virtual I/O Devices

The virt virtual machine contains a small subset of the devices found on an SoC. The available devices will be represented in the device tree passed to the guest at boot. See the table below for a summary of the virtual I/O devices in the virt VM:

Table 592.

Virtual I/O Devices for virt machine	
virt VM **Address, size**	**Descriptions**
0,128MB	space for a flash device (this allows running bootrom code)
0x08000000, 0x20000	Virtual CPU peripherals (including GIC distributor and CPU peripheral space)
0x08000000, 0x10000	Virtual GIC distributor
0x08010000, 0x10000	Virtual GIC CPU interface
0x08020000, 0x10000	Virtul GICv2m controller
0x09000000, 0x10000	Virtual UART
0x09010000, 0x10000	Virtual RTC
0x0a000000..0x0a0001ff	Virtual MMIO
...	Virtual MMIO
0x0c000000, 0x02000000	Virtual platform bus
0x10000000, 0x30000000	virtual PCIE
0x40000000, 30G	guest RAM

11.2.6.4.3 Virtual machine state at initialization

11.2.6.4.3.1 Initial State and Boot

When booting the Host, kernel is entered into the HYP mode for ARMv7 respectively EL2 privillege level for ARMv8. After the boot the kernel uses a stub to install KVM and switches back to SVC, respectively EL1. The virtual machine has no virtualization extensions available, so the guest kernel will be entered in SVC mode (ARMv7) respectively EL1 (ARMv8).

In case of a real hardware the boot program will provide some services before giving control to the OS. The necessary steps needed to be done by the bootloader are described in the kernel documentation: *Documentation/arm/Booting/* (ARMv7), *Documentation/arm64/booting.txt* (ARMv8). In case of virtualization, KVM/QEMU makes the necessary actions to put hardware into the initial state (as seen by the guest) and also will take the role of the bootloader and makes the necessary settings. QEMU also installs a very simple bootloader which just set some registers and after that it jumps to the kernel.

It is recommended that a guest OS be minimally device tree aware. The libfdt library (available with the DTC tool) provides a full range of APIs to parse and manipulate device trees and will make the process of adding device tree awareness to an OS straightforward.

11.2.6.4.3.2 Initial State of Virtual CPUs

In a VM with multiple virtual CPUs, CPU #0 is the boot CPU and all other vcpus in the partition are considered secondary. The boot method for the secondary CPUs is PSCI.

The virtual CPU entry conditions comply with the entry conditions specified by *linux/Documentation/arm/Booting* (ARMv7) or *Documentation/ arm64/booting.txt* (ARMv8)

The virtual CPU state is summarized below:

ARMv7:

- R0 = 0

- R1 = machine type number
- R2 = physical address of device tree block (DTB) in system RAM
- MMU off
- data cache off
- CPSR: 0x000001d3 (SVC mode, asynchronous abort, IRQ and FIQ masked)

ARMv8:

- x0 = physical address of device tree blob (dtb) in system RAM.
- x1 = 0
- x2 = 0
- x3 = 0
- MMU off

11.2.6.4.4 Virtual CPUs

11.2.6.4.4.1 Virtual CPU Specification

Software running in a virtual machine sees a virtual CPU that emulates an ARMv7/ARMv8 core without virtualization extensions.

The virtual CPU type will match that of the host hardware platform.

11.2.6.4.4.2 Time in the Virtual CPU

ARM architecture has an optional extension, the generic timers, which provides:

- a counter (*physical counter*) that measures passing of time in real time
- a timer (*physical timer*) for each CPU. The timer is programmed to raise an interrupt to the CPU after a certain amount of time has passed.

The generic timers include virtualization support by introducing:

- a new counter, the *virtual counter*
- a new timer, the *virtual timer*.

This allows the virtual machine to have direct access to reading (virtual) counters and programming (virtual) timers without trapping.

KVM uses the physical timers in the host, the virtual machine access to the physical timers being disabled.

The virtual machine accesses the virtual timer and can, in this way, directly access the timer hardware without trapping to the hypervisor. However, the virtual timers do not raise virtual interrupts, but hardware interrupts which trap to the hypervisor. KVM injects a corresponding virtual interrupt into the VM when it detects that the virtual timer expired.

11.2.6.4.5 VGIC

The ARM Generic Interrupt Controller (GIC) provides hardware support for virtualization. The guest is able to mask, acknowledge and EOI interrupts without trapping to the hypervisor. However, there is a central part of the GIC called distributor which is responsible for interrupt prioritization and distribution to each CPU which does not provide virtualization extensions and for this part KVM provides an in-kernel emulation. Also, all the physical interrupts cannot be directly received by the guest. Instead, the KVM will program a virtual interrupt which will be raised in the guest. But, with the virtualization support in the GIC controller, when the guest is ACK-ing and EOI-ing the virtual interrupt, there is no need to trap into KVM.

11.2.6.5 Debugging virtual machines

11.2.6.5.1 QEMU Monitor

When starting QEMU, a monitor shell is available that can be used to control and see the state of VM. By default this monitor is started in the Linux shell where QEMU is invoked.

See example below of the output when starting QEMU. The user can interact with the monitor at the (qemu) prompt.

```
QEMU 2.4.0 monitor - type 'help' for more information
(qemu) QEMU waiting for connection on: disconnected:telnet::4446,server
```

The monitor can also be exposed over a network port by using the `-monitor dev` command line option. See Overview of Using QEMU on page 2382 and the QEMU user's manual [1] (see References on page 2376).

Refer to the QEMU user's manual [1] for a complete listing of the monitor commands available. Below is a list of some useful commands supported in the NXP SDK implementation of QEMU:

- **help** - lists all the available commands with usage information
- **info cpus** - displays the state and thread ID of all virtual CPUs
- **info** *registers* - displays the contents of the default vcpu's registers
- **cpu cpu_number** - sets the default vcpu number
- **system_reset** - resets the VM
- **x**/*fmt addr* -- virtual memory dump starting at 'addr'
- **xp**/*fmt addr* -- physical memory dump starting at 'addr'

11.2.6.5.2 QEMU GDB Stub

QEMU supports debugging of a VM using gdb. QEMU contains a gdb stub that can be attached to from a host system and allows standard source level debugging capabilities to examine the state of the VM and do run control.

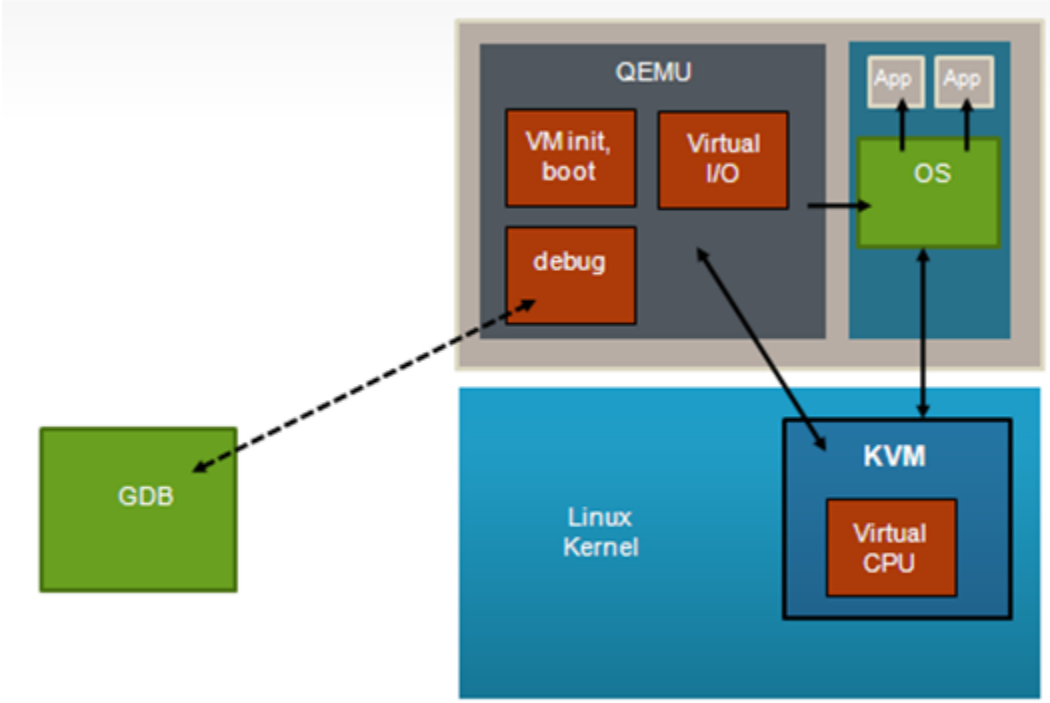

Figure 378.

To use the gdb stub, start QEMU with the -gdb *dev* option where dev specifies the type of connection to be used. See the QEMU user's manual [1] (see References on page 2376) for details.

One useful option when debugging is the -S argument to QEMU which causes QEMU to wait to start the first instruction of the guest until told to start using the monitor (**continue** command).

In the example below the tcp device type is used. A gdb stub will be active on port 4445 of the host Linux kernel when starting QEMU:

```
$ qemu-system-arm -enable-kvm -m 512 -mem-path /var/lib/hugetlbfs/pagesize-2MB -nographic -cpu
host -machine type=virt -kernel /boot/zImage  -serial tcp::4446,server,telnet -initrd /boot/fsl-
image-core-ls1021atwr.ext2.gz -append 'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' -
monitor stdio -gdb tcp::4445

QEMU 2.4.0 monitor - type 'help' for more information
(qemu) QEMU waiting for connection on: telnet:0.0.0.0:4446,server
```

After the guest has been started normally, gdb can be used to connect to the VM (in this example the host kernel has an ip address of 192.168.3.30):

```
(gdb) target remote 192.168.3.30:4445
Remote debugging using 192.168.3.30:4445
0x80024f44 in ?? ()
```

Debugging with gdb can then proceed normally:

```
(gdb) p/x $r15
$2 = 0x80024f44
(gdb)
```

11.2.6.6 KVM/QEMU How-to's

11.2.6.6.1 Quick-start Steps to Build and Deploy KVM Using Yocto

The following steps show how to build host and guest root filesystems, Linux kernel, and QEMU in the Yocto environment.

There are two possibilities to deploy KVM using Yocto:

- Using the preconfigured **fsl-image-virt** Yocto image as the base for host root filesystem. This image type will generate a host root filesystem which contains: QEMU, guest root filesystem and guest kernel image.
- Using other Yocto images as the base for host rootfilesystem . If the user wants to use other Yocto images to enable KVM there will be additional steps needed in order to add all the needed pieces into the host root filesystem: QEMU, guest root filesystem, guest kernel image.

11.2.6.6.1.1 Deploy KVM using fsl-image-virt Image

The host roofs is based on the **fsl-image-virt** image type and the guest rootfs is based on **fsl-image-core**.

The steps outlined below assume that the Yocto build environment is configured so that the **bitbake** command can be run.

1. Build the base host root filesystem using the **fsl-image-virt** image type.

   ```
   $ bitbake fsl-image-virt
   ```

2. Build a kernel with KVM enabled. In this case the same kernel image will be used for both host and guest.

   Configure the Linux kernel to enable KVM-related features (if not enabled by default in the kernel config)

   ```
   $ bitbake -c menuconfig virtual/kernel
   ```

   Follow the steps described in section Quick Start - Recommended Configuration Options on page 2378 to enable KVM in the Linux kernel.

   Then rebuild the kernel based on the new configuration options:

   ```
   $ bitbake virtual/kernel
   ```

3. Re-build the fsl-image-virt image (if nothing was done at step 2, this step may be skipped)

   ```
   bitbake fsl-image-virt
   ```

4. Create the kernel.itb file (if necessary)

   U-boot may use both uImage or FIT image format to load the kernel image. For ARMv7 platforms an uImage is used and for these platforms this step is not needed. For ARMv8, a FIT image is used and the FIT image must be generated. The following steps need to be taken:

   - Update the *fsl-image-kernelitb* to include the rootfs generated by the *fsl-image-virt* (by default the recipee would use the rootfs generated by *fsl-image-core*). In order to change the rootfs type in the generated itb file there are two possible solutions:
     - Redefine the *ROOTFS_IMAGE* variable in *meta-freescale/recipes-fsl/images/fsl-image-kernelitb.bb* directly:

       ```
       -ROOTFS_IMAGE ?= "fsl-image-core"
       +ROOTFS_IMAGE ?= "fsl-image-virt"
       ```

     - Add the following line to *build_<machine_release>/conf/local.conf*:

       ```
       ROOTFS_IMAGE = "fsl-image-virt”
       ```

- Generate the kernel itb:

```
bitbake fsl-image-kernelitb
```

The resulting host rootfs will contain:

- Linux kernel image. Currently for ARMv7 paltforms the zImage file will be included and for ARMv8 platforms the Image file. The kernel image will be located in */boot*
- Guest root filesystem: based on **fsl-image-core**. The guest root file system will be located in */boot*
- QEMU

For steps to run QEMU see the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2394.

11.2.6.6.1.2 Deploy KVM using fsl-image-core Image

The host roofs is based on the **fsl-image-core** image type and the guest rootfs is based on **fsl-image-minimal**.

The steps outlined below assume that the Yocto build environment is configured so that the **bitbake** command can be run.

1. Build the base host root filesystem using the **fsl-image-core** image type.

```
$ bitbake fsl-image-core
```

2. Build a host kernel with KVM-enabled (if not enabled by default in the kernel config)

   Configure the Linux kernel to enable KVM-related features.

```
$ bitbake -c menuconfig virtual/kernel
```

   Follow the steps described in section Quick Start - Recommended Configuration Options on page 2378 to enable KVM in the Linux kernel.

   Then rebuild the kernel based on the new configuration options:

```
$ bitbake virtual/kernel
```

3. Add QEMU to the packages built by **fsl-image-core**.

   Edit the `conf/local.conf` file and append the following line which adds the QEMU package:

```
IMAGE_INSTALL_append = " qemu"
```

4. Build a guest root filesystem and add it to the host rootfs.

   A. Build the guest roofs using the **fsl-image-minimal** image type. This creates a small rootfs sufficient for booting a Linux guest:

```
$ bitbake fsl-image-minimal
```

   This command results in the minimal rootfs being created in tmp/deploy/images. In this example the minimal rootfs built is named: fsl-image-minimal.rootfs.ext2.gz

   B. Use the merge-files feature of Yocto (see Adding Images to a Root Filesystem with Yocto on page 2381) to copy the guest rootfs to the host rootfs.

```
$ mkdir -p meta-freescale/recipes-extended/merge-files/merge-files/merge/home/root
```

```
$ cp tmp/deploy/images/machine/fsl-image-minimal.rootfs.ext2.gz meta-freescale/recipes-extended/
merge-files/merge-files/merge/home/root/guest.rootfs.ext2.gz

$ bitbake -c install -f merge-files

$ bitbake merge-files
```

5. Re-build the fsl-image-core image.

```
bitbake fsl-image-core
```

6. Create the kernel.itb file (if necessary)

   U-boot may use both uImage or FIT image format to load the kernel image. For ARMv7 platforms an uImage is used and for those platforms this step is not needed. For ARMv8, a FIT image is used and the FIT image must be generated.

```
bitbake fsl-image-kernelitb
```

   The resulting host rootfs will contain:

   - Linux kernel image
   - Guest root filesystem
   - QEMU, including the example guest device trees

For steps to run QEMU see the article Quick-start Steps to Run KVM Using Hugetlbfs on page 2394.

11.2.6.6.2 Quick-start Steps to Run KVM Using Hugetlbfs

The pre-requisite to this example is completing the steps in the article Quick-start Steps to Build and Deploy KVM Using Yocto on page 2392.

This example assumes that the host Linux kernel is booted, has a working network interface, and the following images are present in the host root filesystem:

- Guest kernel image (*/boot/zImage* or */boot/Image*)
- Guest root filesystem (*/boot/guest.rootfs.ext2.gz*)
- QEMU (*/usr/bin/qemu-system-arm* or */usr/bin/qemu-system-aarch64*)

There are a number of mechanisms for allocating huge pages and making them accessible via a mount point. Refer to the SDK documentation for details. This example assume allocating pages using the hugeadm command. Create a 512MB pool of 2MB huge pages, which can be used by QEMU for allocating VM memory:

```
$ hugeadm --pool-pages-min 2M:256

 hugeadm --pool-list
 Size  Minimum  Current  Maximum  Default
   2097152      256      256      256        *
```

Create a mount point to access the huge pages:

```
$ hugeadm --create-mounts

$  ls -1 /var/lib/hugetlbfs/
pagesize-2MB
```

Start QEMU specifying the 2MB huge page pool as the file from which to allocate memory. In this example 512MB of memory is allocated to the VM:

32 bit ARMv7:

```
qemu-system-arm -enable-kvm -m 512 -mem-path /var/lib/hugetlbfs/pagesize-2MB -nographic -cpu host -
machine type=virt -kernel /boot/zImage  -serial tcp::4446,server,telnet -initrd /boot/
guest.rootfs.ext2.gz -append 'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' -monitor stdio

QEMU waiting for connection on: telnet::0.0.0.04446,server
```

64bit ARMv8:

```
qemu-system-aarch64 -enable-kvm -m 512 -mem-path /var/lib/hugetlbfs/pagesize-2MB -nographic -cpu
host -machine type=virt -kernel /boot/Image  -serial tcp::4446,server,telnet -initrd /boot/
guest.rootfs.ext2.gz -append 'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' -monitor
stdio

QEMU waiting for connection on: telnet::0.0.0.04446,server
```

Explanation of the command line options:

- **-enable-kvm** : specifies that KVM should be used
- **-m 512** : the amount of memory for the VM
- **-mem-path /var/lib/hugetlbfs/pagesize-2MB** : allocates from hugetlbfs based memory
- **-nographic** : don't instantiate a graphics card, this is the only option supported for the SDK
- **-cpu host** : the type of the CPU. In this case it is the same as the host CPU
- **-machine type=virt** : the type of virtual machine
- **-kernel /boot/zImage** : name of guest Linux kernel
- **-initrd ./boot/guest.rootfs.ext2.gz** : name of guest roofs
- **-append "root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk"** : guest Linux bootargs
- **-serial tcp::4446,server,telne** : provide an emulated serial port (telnet server) on port 4444 on the host Linux system. Default behavior will be for QEMU to wait until the user connects to this port before booting the VM.
- **-monitor stdio** : start QEMU monitor

At this point QEMU is waiting for a telnet connection to the virtual machine's console (port 4446 of the target board) prior to starting the virtual machine.

Connect to QEMU via telnet to start the virtual machine booting. In this example the target board has IP address 192.168.3.30.

```

11.2.6.6.3 How to Use Virtual Network Interfaces Using Virtio

As discussed in Virtual network interfaces on page 2384, there are two aspects of virtual network interfaces-- 1) the "front end" (the device as seen by the guest OS) and 2) the "backend" (the means by the virtual device is connected to the network).

This example uses a "virtio" model NIC card and a tap network backend. The virtual network interface is bridged via a TAP interface to the physical network. The guest OS is Linux.

When starting QEMU we will add the following arguments to create the virtual network interface:

```
-netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=no,ifname="tap0" -device virtio-net-
pci,netdev=tap0
```

Perform the following steps:

1. Enable virtio networking in the host and guest Linux kernels (see Host Kernel: Enabling Virtual Networking on page 2379 and Guest Kernel: Enabling Network and Block Virtual I/O on page 2380).
2. On the host Linux create a bridge to the physical network interface to be used by the virtual network interface in the virtual machine using the **brctl** command. In this example the physical interface being used is eth2:

   ```
   brctl addbr br0
   ifconfig br0 192.168.3.30 netmask 255.255.248.0
   ifconfig eth2 0.0.0.0
   brctl addif br0 eth2
   ```

3. Create a qemu-ifup script on the host Linux system. For the TAP backend type, when QEMU creates the virtual network interface it invokes a user-created script that allows customization of how the TAP interface is to be handled. The name of the TAP interface created by QEMU is passed as an argument. In this example we will bridge the the TAP inteface to the bridge created in step #2. See the example qemu-ifup script below:

   ```
   #!/bin/sh
   # TAP interface will be passed in $1
   bridge=br0
   guest_device=$1
   ifconfig $guest_device 0.0.0.0 up
   brctl addif $bridge $guest_device
   ```

4. When starting QEMU specify that the network device type is "virtio" and specify the path to the script created in step #3:

   ```
   qemu-system-aarch64 -smp 8 -enable-kvm -m 4096 -nographic -cpu host -machine type=virt -kernel /
   boot/Image  -serial tcp::4446,server,telnet -initrd /boot/fsl-image-core-xxxx.ext2.gz -append
   'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' -monitor stdio -netdev
   tap,id=tap0,script=qemu-ifup,downscript=no,ifname="tap0" -device virtio-net-pci,netdev=tap0
   ```

5. In the guest OS the virtual network interface will appear and can be brought up and assigned an IP address in the normal way. In the example below (the commands are run from the guest command shell) the virtio interface is eth0.

   ```
   $ ip addr
   1: lo: <LOOPBACK,UP,LOWER_UP> mtu 65536 qdisc noqueue state UNKNOWN group default
       link/loopback 00:00:00:00:00:00 brd 00:00:00:00:00:00
       inet 127.0.0.1/8 scope host lo
          valid_lft forever preferred_lft forever
       inet6 ::1/128 scope host
          valid_lft forever preferred_lft forever
   2: eth0: <BROADCAST,MULTICAST> mtu 1500 qdisc noop state DOWN group default qlen 1000
       link/ether 52:54:00:12:34:56 brd ff:ff:ff:ff:ff:ff
   ```

```
3: sit0@NONE: <NOARP> mtu 1480 qdisc noop state DOWN group default
    link/sit 0.0.0.0 brd 0.0.0.0

root@ls_machine:~# ethtool -i eth0

bus-info: 0000:00:01.0
supports-statistics: no
supports-test: no
supports-eeprom-access: no
supports-register-dump: no
supports-priv-flags: no

$ ifconfig eth0 192.168.3.31 netmask 255.255.248.0
```

11.2.6.6.4 How to use vhost-net with virtio

vhost-net is a character device that can be used to reduce the number of system calls involved in virtio networking. vhost-net moves network packets between the guest and the host system using the Linux kernel, bypassing QEMU.

In order to use vhost-net perform the following steps:

1. Enable virtio networking and vhost-net in the host and guest Linux kernels (see Host Kernel: Enabling Virtual Networking on page 2379 and Guest Kernel: Enabling Network and Block Virtual I/O on page 2380).
2. On the host Linux create a bridge to the physical network interface to be used by the virtual network interface in the virtual machine using the **brctl** command. In this example the physical interface being used is eth2:

   ```
   brctl addbr br0
   ifconfig br0 192.168.3.30 netmask 255.255.248.0
   ifconfig eth2 0.0.0.0
   brctl addif br0 eth2
   ```

3. Create a qemu-ifup script on the host Linux system. For the TAP backend type, when QEMU creates the virtual network interface it invokes a user-created script that allows customization of how the TAP interface is to be handled. The name of the TAP interface created by QEMU is passed as an argument. In this example we will bridge the the TAP inteface to the bridge created in step #2. See the example qemu-ifup script below:

   ```
   #!/bin/sh
   # TAP interface will be passed in $1
   bridge=br0
   guest_device=$1
   ifconfig $guest_device 0.0.0.0 up
   brctl addif $bridge $guest_device
   ```

4. When starting QEMU specify that the network device type is "virtio" and that vhost-net (**vhost=on** parameter) is used:

   ```
   qemu-system-aarch64 -smp 8 -enable-kvm -m 8192 -mem-path /var/lib/hugetlbfs/pagesize-1GB -
   nographic -cpu host -machine type=virt -kernel /boot/Image  -serial tcp::4446,server,telnet -
   initrd /boot/fsl-image-core-xxxx.ext2.gz -append 'root=/dev/ram0 rw console=ttyAMA0 rootwait
   earlyprintk ramdisk_size=307200' -monitor stdio -netdev tap,id=tap0,script=qemu-
   ifup,downscript=no,ifname="tap0",vhost=on -device virtio-net-pci,netdev=tap0
   ```

5. In the guest the virtual interface will come up as described in How to Use Virtual Network Interfaces Using Virtio on page 2396. In the Host kernel the vhost thread can be seen consuming CPU:

```
 2078 root      20   0       0      0      0 R  93.7  0.0   0:07.09
vhost-2066
 2066 root      20   0 9192660 511632   7532 S  82.0  3.3   0:12.70 qemu-system-
aar
 2091 root      20   0  159636   1092    960 S  68.0  0.0   0:05.50 iperf
```

11.2.6.6.5 How to Use Virtual Disks Using Virtio

As discussed in Virtual block devices on page 2385, there are a number of formats available for virtual disk images.

The example below uses a raw file. The steps below go through the process of creating a virtual disk image, assigning it to a VM, partitioning the disk, creating a filesystem on it, and mounting it.

1. On the host Linux, create a binary image to represent the guest disk. For example to create a 16MB disk:

```
$ dd if=/dev/zero of=my_guest_disk bs=4K count=4K
```

2. Start QEMU, specifying the name of the virtual disk file for the -drive argument:

```
qemu-system-aarch64 -enable-kvm -m 512 -mem-path /var/lib/hugetlbfs/pagesize-2MB -nographic  -
cpu host -machine type=virt -kernel /boot/Image  -serial tcp::4446,server,telnet -initrd /boot/
guest.rootfs.ext2.gz -append 'root=/dev/ram0 rw console=ttyAMA0  rootwait earlyprintk' -monitor
stdio -drive if=none,file=my_guest_disk,cache=none,id=foo,format=raw -device virtio-blk-
pci,drive=foo
```

3. After the guest has booted the virtual disk is visible as a block device in /dev with the name vda, vdb, etc.

```
$ ls -l /dev/vda
brw-rw---- 1 root disk 254, 0 Jan  1  1970 /dev/vda
```

   A virtual block device can be treated like any other hard disk. It can be partitioned, formatted, and mounted.

4. Configure a partition on the disk with fdisk:

```
$ fdisk /dev/vda
Device contains neither a valid DOS partition table, nor Sun, SGI or OSF disklabel
Building a new DOS disklabel. Changes will remain in memory only,
until you decide to write them. After that the previous content
won't be recoverable.
Command (m for help):
```

   Display the partition table:

```

Command (m for help): p

Disk /dev/vda: 16 MB, 16777216 bytes, 32768 sectors
Units = sectors of 1 * 512 = 512 bytes
Sector size (logical/physical): 512 bytes / 512 bytes
I/O size (minimum/optimal): 512 bytes / 512 bytes
Disk label type: dos
Disk identifier: 0xa22daf58

   Device Boot      Start         End      Blocks   Id  System
```

Create a new partition:

```
Command (m for help): n
Partition type:
   p   primary (0 primary, 0 extended, 4 free)
   e   extended
Select (default p): p
Partition number (1-4, default 1): 1
First sector (2048-32767, default 2048): 2048
Last sector, +sectors or +size{K,M,G} (2048-32767, default 32767):
Using default value 32767
Partition 1 of type Linux and of size 15 MiB is set
```

Display the new partition:

```
Disk /dev/vda: 16 MB, 16777216 bytes, 32768 sectors
Units = sectors of 1 * 512 = 512 bytes
Sector size (logical/physical): 512 bytes / 512 bytes
I/O size (minimum/optimal): 512 bytes / 512 bytes
Disk label type: dos
Disk identifier: 0xa22daf58

   Device Boot      Start         End      Blocks   Id  System
/dev/vda1            2048       32767       15360   83  Linux
```

Write the partition table to disk and exit:

```
Command (m for help): w
The partition table has been altered!
Calling ioctl() to re-read partition table
 vda: vda1
```

5. Create a filesystem on the new partition:

```
$ mkfs.ext3 /dev/vda1
mke2fs 1.42.8 (20-Jun-2013)
Filesystem label=
OS type: Linux
Block size=1024 (log=0)
Fragment size=1024 (log=0)
Stride=0 blocks, Stripe width=0 blocks
3840 inodes, 15360 blocks
768 blocks (5.00%) reserved for the super user
First data block=1
Maximum filesystem blocks=15728640
2 block groups
8192 blocks per group, 8192 fragments per group
1920 inodes per group
Superblock backups stored on blocks:
    8193

Allocating group tables: done
Writing inode tables: done
Creating journal (1024 blocks): done
Writing superblocks and filesystem accounting information: done
```

6. Mount the filesystem:

```
$ mount /dev/vda1 /mnt/src
kjournald starting.  Commit interval 5 seconds
EXT3-fs (vda1): using internal journal
EXT3-fs (vda1): mounted filesystem with ordered data mode
```

11.2.6.6.6 How to use virtual disks using virtio-blk-dataplane

Virtio-blk-dataplane was developed for high performance disk I/O, especially for high IOPS devices. The QEMU performs the disk I/O in a dedicated thread that is optimized for I/O performance.

In this example a real disk is used, a block device on the Linux host.

1. Start QEMU:

```
qemu-system-aarch64 -enable-kvm -nographic -machine type=virt -cpu host -kernel /boot/Image -
append "root=/dev/ram rw console=ttyAMA0,115200 ramdisk_size=1000000" -serial tcp::
4444,server,telnet -initrd /boot/fsl-image-core-xxxx.ext2.gz -m 8192 -mem-path /var/lib/
hugetlbfs/pagesize-1GB -object iothread,id=iothread0 -drive
if=none,id=drive0,cache=none,format=raw,file=/dev/sda,aio=native -device virtio-blk-
pci,drive=drive0,scsi=off,iothread=iothread0
```

2. After the guest boots, the virtual disk is visible as a block device with the name vda, vdb, etc.

```
# fdisk -l
Disk /dev/vda: 238.5 GiB, 256060514304 bytes, 500118192 sectors
Units: sectors of 1 * 512 = 512 bytes
Sector size (logical/physical): 512 bytes / 512 bytes
I/O size (minimum/optimal): 512 bytes / 512 bytes
Disklabel type: dos
Disk identifier: 0x000031e0
Device Boot Start End Blocks Id System
/dev/vda1 * 2048 1050623 524288 83 Linux
/dev/vda2 1050624 9439231 4194304 82 Linux swap / Solaris
/dev/vda3 9439232 500117503 245339136 83 Linux
```

In this case the disk has 3 partitions. The partitions can be mounted and used.

11.2.6.6.7 Debugging: How to Examine Initial Virtual Machine State with QEMU

It can be helpful when debugging to examine the state of the virtual machine prior to executing the first instruction of the guest OS.

To do this, start QEMU with the -S option.

Example:

```
qemu-system-aarch64 -enable-kvm -m 512 -nographic -cpu host -machine type=virt -kernel /boot/
Image  -serial tcp::4446,server,telnet -initrd /boot/fsl-image-core-xxxx.ext2.gz -append
'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' -monitor stdio -S
```

The console was started with the "-serial tcp::4446,server,telnet" option so QEMU waits for a connection prior to starting initialization. Use telnet to connect to port 4446 of the target.

At this point QEMU initializes the VM, but does not execute the entry point to the guest OS. The monitor prompt can now be used to examine initial state:

```
QEMU 2.4.0 monitor - type 'help' for more information
(qemu) QEMU waiting for connection on: telnet:0.0.0.0:4446,server
(qemu)
```

To see where boot images are loaded and placed by QEMU use the **info roms** command:

```
(qemu) info roms
addr=0000000040000000 size=0x000028 mem=ram name="bootloader"
addr=0000000040080000 size=0xb9a800 mem=ram name="/boot/Image"
addr=0000000048000000 size=0x1517eef mem=ram name="/boot/fsl-image-core-xxxx.ext2.gz"
addr=0000000049600000 size=0x010000 mem=ram name="dtb"
/rom@etc/acpi/tables size=0x200000 name="etc/acpi/tables"
/rom@etc/table-loader size=0x000880 name="etc/table-loader"
/rom@etc/acpi/rsdp size=0x000024 name="etc/acpi/rsdp"
```

A trivial bootloader is loaded at the start of guest memory at 0x40000000

The kernel image (zImage) is loaded at 0x40080000. The ramdisk is loaded at 0x48000000.

To examine the initial state of registers use the info registers command:

```
(qemu) info registers
PC=0000000040000000  SP=0000000000000000
X00=0000000000000000 X01=0000000000000000 X02=0000000000000000 X03=0000000000000000
X04=0000000000000000 X05=0000000000000000 X06=0000000000000000 X07=0000000000000000
X08=0000000000000000 X09=0000000000000000 X10=0000000000000000 X11=0000000000000000
X12=0000000000000000 X13=0000000000000000 X14=0000000000000000 X15=0000000000000000
X16=0000000000000000 X17=0000000000000000 X18=0000000000000000 X19=0000000000000000
X20=0000000000000000 X21=0000000000000000 X22=0000000000000000 X23=0000000000000000
X24=0000000000000000 X25=0000000000000000 X26=0000000000000000 X27=0000000000000000
X28=0000000000000000 X29=0000000000000000 X30=0000000000000000 PSTATE=400003c5 (flags -Z--)

q00=00000000000000000:0000000000000000 q01=00000000000000000:0000000000000000

q30=00000000000000000:0000000000000000 q31=00000000000000000:0000000000000000
FPCR: 00000000  FPSR: 00000000
```

The program counter is set to 0x40000000 which is the effective address of the entry point of the kernel.

11.2.6.6.8 Debugging: How to Profile Virtualization Overhead with KVM

Running software in a virtual machine can cause additional overhead that affects performance. The virtualization overhead is directly related to the number of times the hypervisor (KVM) is invoked to handle exception conditions that may occur in the virtual machine. These exception handling events are referred to as 'exits', because guest context is exited.

Examples of exits include things such the guest executing a privileged instruction, access a privileged CPU register, accessing a virtual I/O device, or a hardware interrupt such as a decrementer interrupt.

The type and number of exits that occur is workload dependent.

KVM implements a mechanism in which different events are logged. These events are actually tracepoint events, and perf nicely integrates with them. You have to compile the host kernel with the following options:

```
Kernel hacking  --->
     [*] Tracers  --->
         [*]   Trace process context switches and events
```

Counting Events

A count of a subset of KVM events that occur can be seen under debugfs. To see this first mount debugfs:

```
mount -t debugfs none /sys/kernel/debug
```

The statistics can be seen using perf tool:

```
# perf stat -e "kvm:*" -p 1395
^C
 Performance counter stats for process id '1395':

              5678 kvm:kvm_entry
              5678 kvm:kvm_exit
              3121 kvm:kvm_guest_fault
              2278 kvm:kvm_irq_line
                 0 kvm:kvm_mmio_emulate
                 0 kvm:kvm_emulate_cp15_imp
              2438 kvm:kvm_wfi
                 0 kvm:kvm_unmap_hva
                 2 kvm:kvm_unmap_hva_range
                 0 kvm:kvm_set_spte_hva
                 0 kvm:kvm_hvc
              3119 kvm:kvm_userspace_exit
                 0 kvm:kvm_set_irq
                 0 kvm:kvm_ack_irq
              4068 kvm:kvm_mmio
                 0 kvm:kvm_fpu
                 0 kvm:kvm_age_page

      59.316709040 seconds time elapsed
```

Tracing events

Detailed traced can be generated using ftrace:

```
[enable ftrace in kernel: events and system calls]
$echo 1 > /sys/kernel/debug/tracing/events/kvm/enable
$cat /sys/kernel/debug/tracing/trace_pipe

qemu-system-arm-1366  [000] ....   716.115891: kvm_guest_fault: ipa 0x9000000, hsr 0x93430046,

```

11.2.6.6.9 Libvirt KVM/QEMU Example (ARM Architecture)

The following example shows the lifecycle of a simple KVM/QEMU libvirt domain called **kvm**. In this example the default URI is qemu:///system, and because of this default an explicit URI is not used in the virsh commands

Libvirt has the possibility to convert qemu command line arguments in xml. However, the current version of libvirt does not have full support for all qemu arguments. It can be used to generate a basic xml file, but there is currently a problem that it generates a default USB node which should be removed.

1. We begin with a simple QEMU command line in a text file named **kvm.args**:

- 32 bit ARMv7:

```
echo "/usr/bin/qemu-system-arm -name kvm -smp 2 -enable-kvm -m 512  -nographic -cpu host -machine
type=virt -kernel /boot/zImage  -serial pty -initrd /boot/fsl-image-core-ls1021atwr.ext2.gz -
append 'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' " > kvm.args
```

- 64 bit ARMv8:

```
echo "/usr/bin/qemu-system-aarch64 -name kvm -smp 2 -enable-kvm -m 512 -nographic -cpu host -
machine type=virt -kernel /boot/Image  -serial pty -initrd /boot/guest.rootfs.ext2.gz -append
'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' " > kvm.args
```

NOTE

The serial console is a tty, not a telnet server. The -name option is required and specifies the name of the virtual machine.

2. Before defining the domain the QEMU command line must be converted to libvirt XML format:

```
virsh domxml-from-native qemu-argv kvm.args > kvm.xml
```

NOTE

For ARMv7 paltforms the generated xml file has to be manually changed to remove the USB node.

The content of the newly created domain XML file is shown below:

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>12a3391e-9cd4-43dd-b8b7-27b1fb193378</uuid>
  <memory unit='KiB'>524288</memory>
  <currentMemory unit='KiB'>524288</currentMemory>
  <vcpu placement='static'>2</vcpu>
  <os>
    <type machine='virt'>hvm</type>
    <kernel>/boot/zImage</kernel>
    <initrd>/boot/fsl-image-core-ls1021atwr.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-arm</emulator>
    <controller type='usb' index='0'/>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
  </devices>
 </domain>
```

A more complex example including devices can be found bellow.

The example contains two devices:

- a virtio network interface
- a virtio block device (disk)

NOTE

This example will use MMIO as transport for virtio. Currently libvirt has no support for PCI transport, but it can be used using passthrough QEMU command line arguments (see the next example)

Device example (using virtio with MMIO as transport):

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>12a3391e-9cd4-43dd-b8b7-27b1fb193378</uuid>
  <memory unit='KiB'>524288</memory>
  <currentMemory unit='KiB'>524288</currentMemory>
  <vcpu placement='static'>2</vcpu>
  <os>
    <type machine='virt'>hvm</type>
    <kernel>/boot/zImage</kernel>
    <initrd>/boot/fsl-image-core-ls1021atwr.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
```

```
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-arm</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>

    <interface type='ethernet'>
      <mac address='52:54:00:b0:39:28'/>
      <script path='/home/root/qemu-ifup'/>
    </interface>
    <disk type='file' device='disk'>
      <driver name='qemu' type='raw' cache='none'/>
      <source file='/home/root/my_guest_disk'/>
      <target dev='vda' bus='virtio'/>
    </disk>

  </devices>
  <qemu:commandline>
    <qemu:arg value='-mem-path'/>
    <qemu:arg value='/var/lib/hugetlbfs/pagesize-2MB'/>
  </qemu:commandline>
</domain>
```

Device example (using virtio with PCI as transport):

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>faa89ddc-e156-46c0-9d0f-029c322f9bf7</uuid>
  <memory unit='KiB'>1048576</memory>
  <currentMemory unit='KiB'>1048576</currentMemory>
  <vcpu placement='static'>4</vcpu>
  <os>
    <type arch='aarch64' machine='virt'>hvm</type>
    <kernel>/boot/Image</kernel>
    <initrd>/images/fsl-image-core-ls1043ardb.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-aarch64</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
```

```
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
    <memballoon model='none'/>
  </devices>
  <qemu:commandline>

    <qemu:arg value='-netdev'/>
    <qemu:arg value='tap,id=tap0,script=/home/root/qemu-ifup,downscript=no,ifname=tap0'/>
    <qemu:arg value='-device'/>
    <qemu:arg value='virtio-net-pci,netdev=tap0'/>

  </qemu:commandline>
</domain>
```

3. Now the domain can be defined:

```
# virsh define kvm.xml
Domain kvm defined from kvm.xml

# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm                            shut off
```

4. Next start the domain. This starts the VM and boots the guest Linux.

```
# virsh start kvm
Domain kvm started

# virsh list
 Id    Name                           State
----------------------------------------------------
 3     kvm                            running
```

5. The **virsh console** command can be used to connect to the console of the running Linux domain.

```
# virsh console kvm
Connected to domain kvm
Escape character is ^]

Poky (Yocto Project Reference Distro) 1.5 ls1021aqds /dev/ttyAMA0

ls1021aqds login: root
```

6. To stop the domain use the destroy command:

```
# virsh destroy kvm
Domain kvm destroyed

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm                            shut off
```

7. To remove the domain from libvirt, use the undefine command:

```
# virsh undefine kvm
Domain kvm has been undefined

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
```

11.3 Libvirt Users Guide

11.3.1 Introduction to libvirt

11.3.1.1 Overview

This document is a guide and tutorial to using libvirt on NXP SoCs.

Libvirt is an open source toolkit that enables the management of Linux-based virtualization technologies such as KVM/QEMU virtual machines and Linux containers.

The goal of the libvirt project (see http://libvirt.org) is to provide a stable, standard, hypervisor-agnostic interface for managing virtualization "domains" such as virtual machines and containers. Domains can be remote and libvirt provides full security for managing remote domains over a network. Libvirt is a layer intended to be used as a building block for higher level management tools and applications.

Libvirt provides:

- An interface to remotely manage the lifecycle of virtualization domains-- provisioning, start/stop, monitoring
- Support for a variety of hypervisors-- KVM/QEMU and Linux Containers are supported in the NXP SDK
- **libvirtd** -- a Linux daemon that runs on a target node/system and allows a libvirt management tool to manage virtualization domains on the node
- **virsh** -- a basic command shell for managing libvirt domains
- A standard XML format for defining domains

11.3.1.2 For Further Information

Libvirt is an open source project and a great deal of technical and usage information is available on the libvirt.org website:

- http://libvirt.org/index.html

Additional references:

- Architecture: http://libvirt.org/intro.html
- Deployment: http://libvirt.org/deployment.html
- XML Format: http://libvirt.org/format.html
- virsh command reference: http://linux.die.net/man/1/virsh
- The libvirt wiki has user generated content: http://wiki.libvirt.org/page/Main_Page

Mailing Lists

There are three libvirt mailing lists available which can be subscribed to. Archives of the lists are also available.

https://www.redhat.com/archives/libvir-list

https://www.redhat.com/archives/libvirt-users

https://www.redhat.com/archives/libvirt-announce

11.3.1.3 Libvirt in the NXP QorIQ SDK -- Supported Features

The libvirt packages provides a huge number of capabilities and features. This section describes the features tested in the NXP QorIQ SDK release.

The SDK supports QEMU/KVM and LXC and thus supports URIs for QEMU and LXC:

- qemu:///
- lxc:///

The following virsh commands are supported:

- Domain Management
  - *attach-device* - Attach a device from an XML file. To use --config option, then it will effect after the acitive domain restarted.
  - *attach-disk* - attach disk device
  - *attach-interface* - attach network interface
  - *autostart* - configure a domain to be automatically started at boot
  - *blkdeviotune* - set or query a block device I/O tuning parameters.
  - *console* - connect to the console of a domain
  - *cpu-stats* - show domain cpu statistics (need mount /cgroup/cpuacct).
  - *create* - creates a transient domain from an XML file and starts it
  - *define* - define a new persistent domain from an XML file
  - *desc* - show or modify the description and title of a domain
  - *destroy* - For persistent domains, stops the domain. For transient domains, the domain is destroyed. This command does not gracefully stop the domain.
  - *detach-device* - detach a device from an XML file. To use --config option, then it will effect after the acitive domain restarted.
  - *detach-disk* - detach disk device
  - *detach-interface* - detach network interface
  - *domid* - convert a domain name or UUID to domain id.
  - *domif-setlink* - set link state of a virtual interface.
  - *domiftune* - get/set parameters of a virtual interface.
  - *domname* - convert a domain id or UUID to domain name.
  - *domuuid* - convert a domain name or id to domain UUID.
  - *domxml-from-native* - convert a QEMU command line to libvirt XML
  - *domxml-to-native* - convert a libvirt XML file (for QEMU) to a native QEMU command line. Useful for debugging.
  - *dumpxml* - output the XML for the specified domain
  - *edit* - edit XML configuration for a domain.
  - *maxvcpus* - show connection vcpu maximum (for QEMU)
  - *memtune* - get or set memory parameters.
  - *qemu-monitor-command* - for QEMU/KVM domains allows sending commands to the QEMU monitor

- *reset* - reset a domain
- *restore* - restore a domain from a saved state in a file
- *resume* - resume a suspended domain. After *resume* the domain is in the "running" state.
- *save* - save a domain state to a file
- *schedinfo* - show/set scheduler parameters (need mount cgroup CPU controller).
- *setmaxmem* - change maximum memory limit.
- *setmem* - change memory allocation.
- *start* - start a domain
- *suspend* - suspend a running domain. After *suspend* the domain is the "paused" state.
- *ttyconsole* - show tty console.
- *undefine* - remove a domain (undo the effects of *define*)
- *vcpucount* - show domain vcpu counts.
- *vcpuinfo* - show detailed domain vcpu information (for QEMU).
- *vcpupin* - control or query domain vcpu affinity (for QEMU).
- *emulatorpin* - control or query domain emulator affinity.

- Domain Monitoring
  - *domblkerror* - show errors on block devices (for QEMU).
  - *domblkinfo* - show domain block device size information.
  - *domblklist* - list all domain blocks.
  - *domblkstat* - get device block stats for a domain.
  - *domcontrol* - show domain control interface state.
  - *domif-getlink* - get link state of a virtual interface.
  - *domiflist* - list all domain virtual interfaces.
  - *domifstat* - get network interface stats for a domain.
  - *dominfo* - show domain information.
  - *dommemstat* - get memory statistics for a domain.
  - *domstate* - show domain state.
  - *list* - show the status of all domains
- Host and Hypervisor
  - *capabilities* - show capabilities.
  - *hostname* - print the hypervisor hostname.
  - *nodecpumap* - show node cpu map.
  - *nodecpustats* - print cpu stats of the node.
  - *nodeinfo* - show node information.
  - *nodememstats* - print memory stats of the node.
  - *sysinfo* - print the hypervisor sysinfo.
  - *uri* - print the hypervisor canonical URI.
  - *version* - show version.

- Snapshot
  - *snapshot-create* - Create a snapshot from XML
  - *snapshot-create-as* - Create a snapshot from a set of args
  - *snapshot-current* - Get or set the current snapshot
  - *snapshot-delete* - Delete a domain snapshot
  - *snapshot-dumpxml* - Dump XML for a domain snapshot
  - *snapshot-edit* - edit XML for a snapshot
  - *snapshot-info* - snapshot information
  - *snapshot-list* - List snapshots for a domain
  - *snapshot-parent* - Get the name of the parent of a snapshot
  - *snapshot-revert* - Revert a domain to a snapshot
- Virsh itself
  - *cd* - change the current directory.
  - *connect* - (re)connect to hypervisor.
  - *echo* - echo arguments.
  - *exit* - quit this interactive terminal.
  - *help* - print help.
  - *pwd* - print the current directory.
  - *quit* - quit this interactive terminal.

Other virsh commands may operate correctly, but have not been specifically validated in the QorIQ SDK.

11.3.2 Build, Installation, and Configuration

11.3.2.1 Building Libvirt with Yocto

Libvirt is a Linux user space package that can easily be added to a root filesystem using the Yocto build system.

In the NXP SDK, Libvirt and all pre-requisite user space packages are included when building the "virt" and "full" image type:

```
bitbake fsl-image-virt
bitbake fsl-image-full
```

Libvirt can be easily added to any rootfs image by updating the IMAGE_INSTALL_append variable in the **conf/local.conf** file in the Yocto build environment. For example, append the following line to **local.conf**:

```
IMAGE_INSTALL_append = " libvirt libvirt-libvirtd libvirt-virsh"
```

After libvirt is included in a root filesystem the libvirtd daemon will be automatically started by the system init scripts.

11.3.2.2 Running libvirtd

Running libvirtd

The libvirtd daemon is installed as part of a libvirt packages installation. By default the target system init scripts should start libvirtd.

Running libvirtd on the target system is a pre-requisite to running any management tools such as virsh.

The libvirtd daemon can be manually started like this:

```
$ /etc/init.d/libvirtd start
```

In some circumstances the daemon may need to be restarted such as after mounting cgroups or hugetlbfs. Daemon restart can be done like this:

```
$ /etc/init.d/libvirtd restart
```

The libvirtd daemon can be configured in /etc/libvirt/libvirtd.conf. The file is self-documented and has detailed comments on the configuration options available.

The libvird Daemon and Logging

The libvirt daemon logs data to /var/log/libvirt/

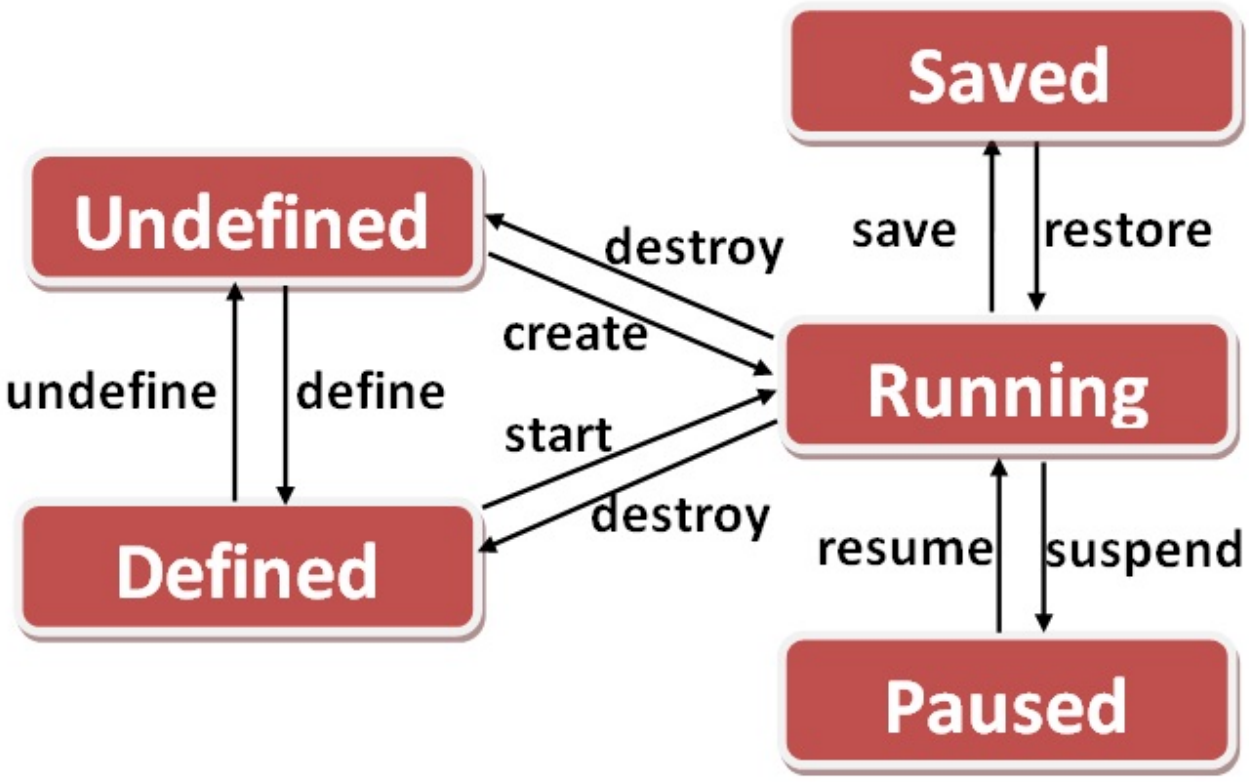
- General libvirtd log messages are in: */var/log/libvirt/libvirtd.log*
- QEMU/KVM domain logs are in: */var/log/libvirt/qemu/[domain-name].log*
- LXC domains logs are in: */var/log/libvirt/lxc/[domain-name].log*

The verbosity of logging can be controlled in */etc/libvirt/libvirtd.conf*.

11.3.2.3 Libvirt Domain Lifecycle

Two types of libvirt domains are supported in the QorIQ SDK-- KVM/QEMU virtual machines and Linux containers.

The following state diagram illustrates the lifecycle of a domain, the states that domains can be in and the **virsh** commands that move the domain between states.



Domain States

1. *Undefined*

There are two types of domains-- persistent and transient domains. All domains begin in the "undefined" state where they are defined in XML definition file, and libvirt is unaware of them.

2. *Defined*

Persistent domains begin with being "defined". This adds the domain to libvirt, but it is not running. This state can also be conceptually thought of as "stopped". The output of **virsh list --all** shows the domain as being "shut off".

3. *Running*

The "running" state is the normal state of an active domain after it has been started. The **start** command is used to move persistent domains into this state. Transient domains go from being undefined to "running" through the **create** command.

4. *Paused*

The domain execution has been suspended. The domain is unaware of being in this state.

5. *Saved*

The domain state has been saved and could be restored again.

See the Libvirt KVM/QEMU Example (Power Architecture) on page 2367 article for an example of a KVM/QEMU domain lifecycle.

See the Basic Example on page 2421 article for an example of a container domain lifecycle.

11.3.2.4 Libvirt URIs

Because libvirt supports managing multiple types of virtualization domains (possibly remote) it uses uniform resource identifiers (URIs) to describes the target "node" to manage and the type of domain being managed.

A URI is specified when tools such as **virsh** makes a connection to a target node running **libvirtd**.

Two types of URIs are supported in the QorIQ SDK-- QEMU/KVM and LXC.

QEMU/KVM URIs are in the form:

- For a local node: *qemu:///system*
- For a remote node: *qemu[+transport]://[hostname]/system*

For Linux containers:

- For a local node: *lxc:///*
- For a remote node: *lxc[+transport]://[hostname]/*

A default URI can be specified in the environment (LIBVIRT_DEFAULT_URI) or in the /etc/libvirt/libvirtd.conf config file.

For further information about URIs:

- http://libvirt.org/uri.html
- http://libvirt.org/remote.html#Remote_URI_reference

11.3.2.5 virsh

The virsh command is a command line tool provided with the libvirt package for managing libvirt domains. It can be used to create, start, pause, shutdown domains. The general command format is:

```
virsh [OPTION]... <command> <domain> [ARG]...
```

11.3.2.6 Libvirt xml

The libvirt XML format is defined at: http://libvirt.org/format.html.

11.3.3 Examples

11.3.3.1 KVM Examples

11.3.3.1.1 Libvirt KVM/QEMU Example (Power Architecture)

The following example shows the lifecycle of a simple KVM/QEMU libvirt domain called *kvm1*.

In this example the default URI is qemu:///system, and because of this default an explicit URI is not used in the virsh commands.

1. We begin with a simple QEMU command line in a text file named kvm1.args:

```
$ cat kvm1.args
/usr/bin/qemu-system-ppc -m 256 -nographic -M ppce500 -kernel /boot/uImage -initrd /home/root/
my.rootfs.ext2.gz -append "root=/dev/ram rw console=ttyS0,115200" -serial pty -enable-kvm -name kvm1
$
```

NOTE

The serial console is a tty, not a telnet server. The -name option is required and specifies the name of the virtual machine.

2. Before defining the domain the QEMU command line must be converted to libvirt XML format:

```
$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$
```

The content of the newly created domain XML file is shown below:

```
$ cat kvm1.xml
<domain type='kvm'>
  <name>kvm1</name>
  <uuid>f5b7cf86-41eb-eb78-4284-16501ff9f0e1</uuid>
  <memory unit='KiB'>262144</memory>
  <currentMemory unit='KiB'>262144</currentMemory>
  <vcpu placement='static'>1</vcpu>
  <os>
    <type arch='ppc' machine='ppce500'>hvm</type>
    <kernel>/boot/uImage</kernel>
    <initrd>/home/root/my.rootfs.ext2.gz</initrd>
    <cmdline>root=/dev/ram rw console=ttyS0,115200</cmdline>
  </os>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-ppc</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
```

```
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
    <memballoon model='virtio'/>
  </devices>
</domain>
```

3. Now the domain can be defined:

```
# virsh define kvm1.xml
Domain kvm1 defined from kvm1.xml

# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm1                           shut off
```

4. Next start the domain. This starts the VM and boots the guest Linux.

```
# virsh start kvm1
Domain kvm1 started

# virsh list
 Id    Name                           State
----------------------------------------------------
 3     kvm1                           running
```

5. The virsh console command can be used to connect to the console of the running Linux domain.

```
# virsh console kvm1
Connected to domain kvm1
Escape character is ^]

Poky 9.0 (Yocto Project 1.4 Reference Distro) 1.4 model : qemu ppce500 ttyS0

model : qemu ppce500 login:
```

Press CTRL +] to exit the console.

6. To stop the domain use the destroy command:

```
# virsh destroy kvm1
Domain kvm1 destroyed

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm1                           shut off
```

7. To remove the domain from libvirt, use the undefine command:

```
# virsh undefine kvm1
Domain kvm1 has been undefined

root@p4080ds:~# virsh list --all
 Id    Name                           State
```

```
-------------------------------------------------
```

11.3.3.1.2 Libvirt KVM/QEMU -- Adding Devices Example (Power Architecture)

This example shows how devices (virtual network, USB, and PCI) can be added to a libvirt domain. The steps are identical to the simple domain example shown in Libvirt KVM/QEMU Example (Power Architecture) on page 2367 , (except some additional preparation is needed for step #1):

1. Create a text file containing the QEMU command line
2. Use **virsh domxml-from-native** to create the libvirt XML
3. Use **virsh define** to define the QEMU domain
4. Use **virsh start** to start the domain

When defining the QEMU command line options in step #1 to add the network, USB, and PCI devices it is necessary to explicitly specify the PCI slot number for each device (all the devices in this example appear on the VM's virtual PCI bus). The remainder of this example explains how to do this.

The normal QEMU command line arguments to assign these devices to a virtual machine would look something like:

- for a virtual network interface

```
-netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -
device virtio-net-pci,netdev=tap0
```

- for the passthrough of USB device on bus #2, port #1

```
-device usb-ehci,id=ehci -device usb-host,bus=ehci.0,hostbus=2,hostport=1
```

- for the passthrough of PCI device 0000:01:00.0

```
-device vfio-pci,host=0000:01:00.0
```

(For further information on these command line argument, please refere to the KVM/QEMU documentation)

All these devices will appear on the virtual PCI bus in the virtual machine. However, in the context of libvirt it is necessary to explicitly assign the PCI slot for each device and therefore it is necessary to determine what slot are occupied and free.

First, start the virtual machine with libvirt **without the new devices** so that the default PCI slot assignment can be viewed (the example is for a domain called "kvm1" on a p4080ds):

```
$ echo '/usr/bin/qemu-system-ppc -m 512 -nographic -M ppce500 -kernel /home/root/uImage -initrd /
home/root/fsl-image-minimal-p4080ds.rootfs.ext2.gz  -append "root=/dev/ram rw
console=ttyS0,115200" -enable-kvm -smp 8 -mem-path /var/lib/hugetlbfs/pagesize-16MB -name kvm1 -
serial pty' > kvm1.args

$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$ virsh define kvm1.xml
$ virsh start kvm1
```

Next, view the devices on the PCI bus:

```
$ virsh qemu-monitor-command --hmp kvm1 'info pci'
  Bus  0, device   0, function 0:
    PCI bridge: PCI device 1957:0030
      BUS 0.
      secondary bus 0.
```

```
      subordinate bus 0.
      IO range [0x0000, 0x0fff]
      memory range [0x00000000, 0x000fffff]
      prefetchable memory range [0x00000000, 0x000fffff]
      BAR0: 32 bit memory at 0xc0000000 [0xc00fffff].
      id ""
  Bus  0, device   1, function 2:
    USB controller: PCI device 8086:7020
      IRQ 0.
      BAR4: I/O at 0xffffffffffffffff [0x001e].
      id "usb"
  Bus  0, device   3, function 0:
    Class 0255: PCI device 1af4:1002
      IRQ 0.
      BAR0: I/O at 0x1000 [0x101f].
      id "balloon0"
```

In this example it can be seen that the highest occupied slot is 0x3, which means that slots 0x4 and higher are available.

The explicit definition of the PCI slot numbers on the QEMU command line looks like this:

- for a virtual network interface (PCI slot/addr 0x4)

```
-netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-ifdown,vhost=on -
device virtio-net-pci,netdev=tap0,bus=pci.0,addr=0x4
```

- for the passthrough of USB device on bus #2, port #1 (PCI slot/addr 0x5)

```
-device usb-ehci,id=ehci,bus=pci.0,addr=0x5 -device usb-host,bus=ehci.0,hostbus=2,hostport=1
```

- for the passthrough of PCI device 0000:01:00.0 (PCI slot/addr 0x6)

```
-device vfio-pci,host=0000:01:00.0,bus=pci.0,addr=0x06
```

The virtual machine's PCI bus is "pci.0".

The complete command sequence to define the domain and start it looks like:

```
$ echo '/usr/bin/qemu-system-ppc -m 512 -nographic -M ppce500 -kernel /home/root/uImage -initrd /
home/root/fsl-image-minimal-p4080ds.rootfs.ext2.gz  -append "root=/dev/ram rw
console=ttyS0,115200" -enable-kvm -smp 8 -mem-path /var/lib/hugetlbfs/pagesize-16MB -name kvm1 -
serial pty -netdev tap,id=tap0,script=/home/root/qemu-ifup,downscript=/home/root/qemu-
ifdown,vhost=on -device virtio-net-pci,netdev=tap0,bus=pci.0,addr=0x4 -device usb-
ehci,id=ehci,bus=pci.0,addr=0x5 -device usb-host,bus=ehci.0,hostbus=2,hostport=1 -device vfio-
pci,host=0000:01:00.0,bus=pci.0,addr=0x06' > kvm1.args

$ virsh domxml-from-native qemu-argv kvm1.args  > kvm1.xml
$ virsh define kvm1.xml
$ virsh start kvm1
```

Libvirt also supports adding devices into a domain by modifying the domain XML file directly.

Shutdown the guest domain and edit the guest XML definition with the virsh edit command

```
$ virsh edit kvm1
```

- for a virtual network interface (PCI slot/addr 0x4)

```
<interface type="ethernet">
  <script path="/home/root/qemu-ifup"/>
```

```
  <model type="virtio"/>
  <driver name="vhost"/>
  <address type='pci' domain='0x0000' bus='0x00' slot='0x04' function='0x0'/>
</interface>
```

- for the passthrough of PCI device 0000:01:00.0 (PCI slot/addr 0x6)

```
<hostdev mode="subsystem" type="pci" managed="yes">
  <driver name="vfio"/>
  <source>
    <address domain="0x0000" bus="0x01" slot="0x06" function="0x0"/>
  </source>
</hostdev>
```

Start the domain again.

It is also possible to add and remove devices by defining the devicde in a standalone XML file. The **virsh attach-device/ detach-device** commands commands can be used when the domain is not active.

For example,

```
$ cat vhost_on.xml
<interface type='ethernet'>
  <script path='/home/root/qemu-ifup'/>
  <model type='virtio'/>
  <driver name='vhost'/>
  <address type='pci' domain='0x0000' bus='0x00' slot='0x04' function='0x0'/>
</interface>
```

Attach device to the guest domain using **virsh attach-device.** The resulting XML file can be dumped to find the added device:

```
$ virsh attach-device --config kvm1 vhost_on.xml
$ virsh dumpxml kvm1
```

11.3.3.1.3 Libvirt KVM/QEMU Example (ARM Architecture)

The following example shows the lifecycle of a simple KVM/QEMU libvirt domain called **kvm**. In this example the default URI is qemu:///system, and because of this default an explicit URI is not used in the virsh commands

Libvirt has the possibility to convert qemu command line arguments in xml. However, the current version of libvirt does not have full support for all qemu arguments. It can be used to generate a basic xml file, but there is currently a problem that it generates a default USB node which should be removed.

1. We begin with a simple QEMU command line in a text file named **kvm.args**:

- 32 bit ARMv7:

```
echo "/usr/bin/qemu-system-arm -name kvm -smp 2 -enable-kvm -m 512  -nographic -cpu host -machine
type=virt -kernel /boot/zImage  -serial pty -initrd /boot/fsl-image-core-ls1021atwr.ext2.gz -
append 'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' " > kvm.args
```

- 64 bit ARMv8:

```
echo "/usr/bin/qemu-system-aarch64 -name kvm -smp 2 -enable-kvm -m 512 -nographic -cpu host -
machine type=virt -kernel /boot/Image  -serial pty -initrd /boot/guest.rootfs.ext2.gz -append
'root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk' " > kvm.args
```

NOTE

The serial console is a tty, not a telnet server. The -name option is required and specifies the name of the virtual machine.

2. Before defining the domain the QEMU command line must be converted to libvirt XML format:

```
virsh domxml-from-native qemu-argv kvm.args > kvm.xml
```

NOTE

For ARMv7 paltforms the generated xml file has to be manually changed to remove the USB node.

The content of the newly created domain XML file is shown below:

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>12a3391e-9cd4-43dd-b8b7-27b1fb193378</uuid>
  <memory unit='KiB'>524288</memory>
  <currentMemory unit='KiB'>524288</currentMemory>
  <vcpu placement='static'>2</vcpu>
  <os>
    <type machine='virt'>hvm</type>
    <kernel>/boot/zImage</kernel>
    <initrd>/boot/fsl-image-core-ls1021atwr.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-arm</emulator>
    <controller type='usb' index='0'/>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
  </devices>
 </domain>
```

A more complex example including devices can be found bellow.

The example contains two devices:

- a virtio network interface
- a virtio block device (disk)

NOTE

This example will use MMIO as transport for virtio. Currently libvirt has no support for PCI transport, but it can be used using passthrough QEMU command line arguments (see the next example)

Device example (using virtio with MMIO as transport):

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>12a3391e-9cd4-43dd-b8b7-27b1fb193378</uuid>
  <memory unit='KiB'>524288</memory>
  <currentMemory unit='KiB'>524288</currentMemory>
  <vcpu placement='static'>2</vcpu>
  <os>
    <type machine='virt'>hvm</type>
    <kernel>/boot/zImage</kernel>
    <initrd>/boot/fsl-image-core-ls1021atwr.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-arm</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>

    <interface type='ethernet'>
      <mac address='52:54:00:b0:39:28'/>
      <script path='/home/root/qemu-ifup'/>
    </interface>
    <disk type='file' device='disk'>
      <driver name='qemu' type='raw' cache='none'/>
      <source file='/home/root/my_guest_disk'/>
      <target dev='vda' bus='virtio'/>
    </disk>

  </devices>
  <qemu:commandline>
    <qemu:arg value='-mem-path'/>
    <qemu:arg value='/var/lib/hugetlbfs/pagesize-2MB'/>
  </qemu:commandline>
</domain>
```

Device example (using virtio with PCI as transport):

```
<domain type='kvm' xmlns:qemu='http://libvirt.org/schemas/domain/qemu/1.0'>
  <name>kvm</name>
  <uuid>faa89ddc-e156-46c0-9d0f-029c322f9bf7</uuid>
  <memory unit='KiB'>1048576</memory>
  <currentMemory unit='KiB'>1048576</currentMemory>
  <vcpu placement='static'>4</vcpu>
  <os>
    <type arch='aarch64' machine='virt'>hvm</type>
    <kernel>/boot/Image</kernel>
```

```
    <initrd>/images/fsl-image-core-ls1043ardb.ext2.gz</initrd>
    <cmdline>root=/dev/ram0 rw console=ttyAMA0 rootwait earlyprintk</cmdline>
  </os>
  <cpu mode='custom' match='exact'>
    <model fallback='allow'>host</model>
  </cpu>
  <clock offset='utc'/>
  <on_poweroff>destroy</on_poweroff>
  <on_reboot>restart</on_reboot>
  <on_crash>destroy</on_crash>
  <devices>
    <emulator>/usr/bin/qemu-system-aarch64</emulator>
    <serial type='pty'>
      <target port='0'/>
    </serial>
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
    <memballoon model='none'/>
  </devices>
  <qemu:commandline>

    <qemu:arg value='-netdev'/>
    <qemu:arg value='tap,id=tap0,script=/home/root/qemu-ifup,downscript=no,ifname=tap0'/>
    <qemu:arg value='-device'/>
    <qemu:arg value='virtio-net-pci,netdev=tap0'/>

  </qemu:commandline>
</domain>
```

3. Now the domain can be defined:

```
# virsh define kvm.xml
Domain kvm defined from kvm.xml

# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm                            shut off
```

4. Next start the domain. This starts the VM and boots the guest Linux.

```
# virsh start kvm
Domain kvm started

# virsh list
 Id    Name                           State
----------------------------------------------------
 3     kvm                            running
```

5. The **virsh console** command can be used to connect to the console of the running Linux domain.

```
# virsh console kvm
Connected to domain kvm
Escape character is ^]

Poky (Yocto Project Reference Distro) 1.5 ls1021aqds /dev/ttyAMA0
```

```
ls1021aqds login: root
```

6. To stop the domain use the destroy command:

```
# virsh destroy kvm
Domain kvm destroyed

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
 -     kvm                            shut off
```

7. To remove the domain from libvirt, use the undefine command:

```
# virsh undefine kvm
Domain kvm has been undefined

root@p4080ds:~# virsh list --all
 Id    Name                           State
----------------------------------------------------
```

11.3.3.2 Libvirt_lxc Examples

11.3.3.2.1 Basic Example

The following example shows the lifecycle of a simple LXC libvirt domain called *container1*. The virsh tool is used for managing the lxc domain lifecycle.

1. Confirm the host Linux configuration. Begin by confirming that the host kernel is configured correctly and that rootfs setup such as mounting cgroups has been done. This can be done with the lxc-checkconfig command.

```
# lxc-checkconfig
--- Namespaces ---
Namespaces: enabled
Utsname namespace: enabled
Ipc namespace: enabled
Pid namespace: enabled
User namespace: missing
Network namespace: enabled
Multiple /dev/pts instances: enabled

--- Control groups ---
Cgroup: enabled
Cgroup clone_children flag: enabled
Cgroup device: enabled
Cgroup sched: enabled
Cgroup cpu account: enabled
Cgroup memory controller: enabled
Cgroup cpuset: enabled

--- Misc ---
Veth pair device: enabled
Macvlan: enabled
Vlan: enabled
File capabilities: enabled
```

2. **Create a libvirt XML file defining the container**. The example below shows a very simple container defined in container1.xml that runs the command /bin/sh and has a console:

```
# cat container1.xml
<domain type='lxc'>
  <name>container1</name>
  <memory>500000</memory>
  <os>
    <type>exe</type>
    <init>/bin/sh</init>
  </os>
  <devices>
    <console type='pty'/>
  </devices>
</domain>
```

3. **Define the container.** The *virsh define* command processes the XML and makes creates the new libvirt domain.

```
# virsh -c lxc:/// define container1.xml
Domain container1 defined from container1.xml

# virsh -c lxc:/// list --all
 Id    Name                           State
----------------------------------------------------
 -     container1                     shut off
```

4. Start the container.

```
# virsh -c lxc:/// start container1
Domain container1 started

# virsh -c lxc:/// list
 Id    Name                           State
----------------------------------------------------
 3196  container1                     running
```

5. Connect to the console.

```
# virsh -c lxc:/// console container1
Connected to domain container1
Escape character is ^]
sh-4.2#
sh-4.2# ps -ef
UID        PID  PPID  C STIME TTY          TIME CMD
root         1     0  0 18:25 pts/2    00:00:00 /bin/sh
root         3     1  0 18:36 pts/2    00:00:00 ps -ef

sh-4.2# ifconfig br0
br0: flags=4163<UP,BROADCAST,RUNNING,MULTICAST>  mtu 1500
        inet 10.171.73.123  netmask 255.255.254.0  broadcast 10.171.73.255
        inet6 fe80::a00:27ff:fe01:fe07  prefixlen 64  scopeid 0x20<link>
        ether 08:00:27:01:fe:07  txqueuelen 0  (Ethernet)
        RX packets 865838  bytes 104029354 (99.2 MiB)
        RX errors 0  dropped 0  overruns 0  frame 0
        TX packets 104446  bytes 43998714 (41.9 MiB)
        TX errors 0  dropped 0 overruns 0  carrier 0  collisions 0
```

```
sh-4.2#
```

Press CTRL +] to exit the console.

The following aspects must be noted:

- the processes inside the container are running in a separate namespace, hence the different process hierarchy
- since no network configuration for the domain is explicitly specified, all networking interfaces are shared with the host (all the other interfaces are present too - br0 is mentioned as an example)
- since no filesystem configuration is specified for the domain, the filesystem is shared with the host-- all host mounts are present in the container as well.

6. To stop the container use the destroy command:

```
# virsh -c lxc:/// destroy container1
Domain container1 destroyed

# virsh -c lxc:/// list  --all
 Id    Name                           State
----------------------------------------------------
 -     container1                     shut off
```

7. To remove the domain from libvirt, use the undefine command.

```
# virsh -c lxc:/// undefine container1
Domain container1 has been undefined
```

11.3.3.2.2 Custom Container Filesystem

The libvirt documentation (http://libvirt.org/formatdomain.html#elementsFilesystems) details the flavors and usage of the **filesystem** tag in order to assign particular types of filesystem mounts to the domain.

Mounts

The <mount> tag specifies private root filesystem, available on host in a specific directory. It will be the rootfs of the container. The filesystem can be handcrafted, installed from media, debootstrapped, etc. Below is an example snippet of the XML that assigns a filesystem to a container:

```
<domain type='lxc'>
  [ ... ]
  <devices>
    [ ... ]
    <filesystem type='mount'>
      <source dir='/var/lib/lxc/foo/rootfs'/>
      <target dir='/'/>
    </filesystem>
  </devices>
</domain>
```

The result is that the domain is started with the root mounted at */var/lib/lxc/foo/rootfs*.

For ease of use, the example that follows will use the standard LXC command lxc-create to build a container Busybox rootfs. However, the default rootfs created by lxc-create will not work with libvirt tools as-is, and some additional terminal setup must be done. This will be detailed in the next example: Container Terminal Setup on page 2424.

Please note that, if you're planning to use this LXC built rootfs with libvirt containers, you will also have to bind-mount the host library directories. These vary depending on whether the libraries are 32bit, 64 bit or both. Basically, you will have to bind-mount all the available library dirs among **/lib, /usr/lib, /lib64, /urs/lib64**, using entries like the one below:

```
<domain type='lxc'>
  [ ... ]
  <devices>
    [ ... ]
    <filesystem type='mount'>
      <source dir='/lib'/>
      <target dir='/lib'/>
      <readonly />
    </filesystem>
  </devices>
</domain>
```

11.3.3.2.3 Container Terminal Setup

Each LXC domain needs at least one console device defined in the XML. By default, libvirt will link this console to the process and make it available with **virsh console** command.

Libvirt also offers support for multiple consoles in a container. This section provides an example describing how libvirt can be used to start four processes inside the container and assign each one of these a private terminal. This will be done by using:

- a Busybox container filesystem, built with lxc-create
- a modified inittab
- the container XML configuration

Libvirt will mount a tmpfs on /dev and a devpts on /dev/pts and it will create all the device nodes itself inside the domain. The domain definition will be altered so that it will start the busybox-init as the init process.

The init process reads the /etc/inittab file inside the rootfs and will determine additional processes to start, and the terminals to link them to. Here is an example inittab that specifies the four processes to start and the separate tty device assigned to each:

```
::sysinit:/etc/init.d/rcS
tty1::askfirst:/bin/sh
tty2::respawn:/bin/getty -L tty2 115200 vt100
tty3::respawn:/bin/getty -L tty3 115200 vt100
tty4::respawn:/bin/getty -L tty4 115200 vt100
```

The domain XML configuration that shows the /sbin/init as the initial program to run and describes the four tty devices looks like this:

```
<domain type='lxc'>
  [ ... ]
  <os>
    <type>exe</type>
    <init>/sbin/init</init>
  </os>
  [ ... ]
  <devices>
    [ ... ]
    <console type='pty'>
      <target type='serial' port='0'/>
    </console>
```

```
    <console type='pty'>
      <target type='serial' port='1'/>
    </console>
    <console type='pty'>
      <target type='serial' port='2'/>
    </console>
    <console type='pty'>
      <target type='serial' port='3'/>
    </console>
  </devices>
</domain>
```

Using the inittab above and XML configs, **virsh start** will start the following process hierarchy:

```
# ps axf
[ ... ]
18450 ?        Ss  0:00 /usr/libexec/libvirt_lxc --name foo --console 24 --console 25 --console 26
--console 27 --security=selinux --handshake 30 --background
18451 pts/0    Ss+ 0:00  \_ init
18454 ?        Ss  0:00      \_ /bin/syslogd
18459 ?        Ss  0:00      \_ /bin/sh
18460 pts/1    Ss+ 0:00      \_ /bin/getty -L tty2 115200 vt100
18461 pts/2    Ss+ 0:00      \_ /bin/getty -L tty3 115200 vt100
18462 pts/3    Ss+ 0:00      \_ /bin/getty -L tty4 115200 vt100
```

By running **virsh -c lxc:/// dumpxml foo**, we can see what alias libvirt has assigned to each console device:

```
<domain type='lxc' id='18450'>
  [ ... ]
  <devices>
    [ ... ]
    <console type='pty' tty='/dev/pts/3'>
      <source path='/dev/pts/3'/>
      <target type='serial' port='0'/>
      <alias name='console0'/>
    </console>
    <console type='pty'>
      <source path='/dev/pts/4'/>
      <target type='serial' port='1'/>
      <alias name='console1'/>
    </console>
    <console type='pty'>
      <source path='/dev/pts/5'/>
      <target type='serial' port='2'/>
      <alias name='console2'/>
    </console>
    <console type='pty'>
      <source path='/dev/pts/6'/>
      <target type='serial' port='3'/>
      <alias name='console3'/>
    </console>
  </devices>
</domain>
```

To connect to a particular console, one must run

```
virsh -c lxc:/// console --devname <console_alias> <domain_name>
```

```
[root@everest][~]# virsh -c lxc:/// console --devname console2 foo
Connected to domain foo
Escape character is ^]

everest.ea.freescale.net login: root
#
#
#
```

11.3.3.2.4 Networking Examples

Libvirt offers extensive support when it comes to networking. The purpose of this section is to provide some insight of how standard LXC networking scenarios can be achieved with Libvirt - to provide the same functionality. In its further versions, this document could include details regarding other, more advanced networking options as well.

11.3.3.2.4.1 Shared Networking

Shared Networking

By default libvirt containers share network interfaces and the network namespace with the host. To share the hosts network interfaces, simply do not define any network interfaces in the domain XML.

When at least one interface is defined, the container will be started in a new network namespace, with the defined interface and a loopback.

No Networking

In order to remove all access to the host's network interfaces, start the container in a new network namespace, without specifying any interface. To do this use the <privnet> XML tag as seen in the example below. This will a loopback interface in the new namespace, but the host network interfaces are not visible in the container.

```
<domain type='lxc'>
  [ ... ]
  <features>
    <privnet/>
  </features>
</domain>
```

11.3.3.2.4.2 Ethernet Bridging

This is the recommended configuration for general guest activity on hosts with static wired networking configurations. It relies on 802.1d Ethernet Bridging, and it provides a bridge from the VM directly into the LAN. This assumes there is a bridge device on the host with one or more of the host's physical NICs enslaved to it. The guest VM will have an associated tun device created with a name of vnetN, which can also be overridden with the **target** element in the XML config file. This tun device will also be enslaved to the bridge. The IP range / network configuration is whatever is used on the LAN. This provides the guest VM full incoming and outgoing net access just like a physical machine. The bridge normally is a Linux bridge - but this can be configured to be an open vSwitch as well, if it is supported on the host. This is done by adding some further parameters in the config file.

Host Configuration

The physical interface **fm1-gb1** is added to a bridge device - **br0**:

```
ifconfig fm1-gb1 0.0.0.0 up
brctl addbr br0
ifconfig br0 192.168.1.141 up
brctl addif br0
```

XML Description of the Interface

Only the relevant part is described here - defining the interface of the guest in XML:

```
<domain type='lxc'>
  [ ... ]
  <devices>
    [ ... ]
    <interface type="bridge">
      <source bridge="br0" />
    </interface>
  </devices>
</domain>
```

Guest Configuration and Testing

After booting the container the network interface can be managed normally:

```
~ # ifconfig
eth0      Link encap:Ethernet  HWaddr 52:54:00:83:78:F4
          inet6 addr: fe80::5054:ff:fe83:78f4/64 Scope:Link
          UP BROADCAST RUNNING MULTICAST  MTU:1500  Metric:1
          RX packets:22 errors:0 dropped:0 overruns:0 frame:0
          TX packets:8 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:3104 (3.0 KiB)  TX bytes:636 (636.0 B)

lo        Link encap:Local Loopback
          inet addr:127.0.0.1  Mask:255.0.0.0
          inet6 addr: ::1/128 Scope:Host
          UP LOOPBACK RUNNING  MTU:16436  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0
          TX packets:0 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:0
          RX bytes:0 (0.0 B)  TX bytes:0 (0.0 B)

~ # ifconfig eth0 192.168.1.143
~ # ping -c 3 192.168.1.1 # gateway
PING 192.168.1.1 (192.168.1.1): 56 data bytes
64 bytes from 192.168.1.1: seq=0 ttl=64 time=3.557 ms
64 bytes from 192.168.1.1: seq=1 ttl=64 time=0.220 ms
64 bytes from 192.168.1.1: seq=2 ttl=64 time=0.227 ms

--- 192.168.1.1 ping statistics ---
3 packets transmitted, 3 packets received, 0% packet loss
round-trip min/avg/max = 0.220/1.334/3.557 ms

PING 192.168.1.141 (192.168.1.141): 56 data bytes
64 bytes from 192.168.1.141: seq=0 ttl=64 time=3.493 ms
64 bytes from 192.168.1.141: seq=1 ttl=64 time=0.050 ms
64 bytes from 192.168.1.141: seq=2 ttl=64 time=0.036 ms

--- 192.168.1.141 ping statistics ---
3 packets transmitted, 3 packets received, 0% packet loss
round-trip min/avg/max = 0.036/1.193/3.493 ms
~ #
```

11.3.3.2.4.3 MACVLAN

Macvlan is a relatively new Linux kernel technology used to ease the task of networking in virtual machines. See the following article for some useful overview information: http://seravo.fi/2012/virtualized-bridged-networking-with-macvtap.

Macvlan is device driver consisting of 2 components:

- the **macvlan** driver - which makes it possible to create **virtual network interfaces** that "cling on" a physical network interface. Each virtual interface has its own MAC address distinct from the physical interface's MAC address. Frames sent to or from the virtual interfaces are mapped to the physical interface, which is called **the lower interface**.
- the **tap** interface - a software-only interface, using to pass Ethernet frames. Instead of passing frames to and from a physical Ethernet card, the frames are read and written by a userspace program. The kernel makes the Tap interface available via the */dev/tapN* device file, where N is the index of the network interface.

Libvirt uses the macvtap device technology to attach virtual network interfaces to physical ones. This has no impact on the functionality of the physical interfaces on the host. The macvtap device has a different approach than the bridge. While the latter provides connectivity from the host to the virtual devices, the former isolates them. The bridge unifies the physical interface with the virtual ones, thus providing a common addressing space and connectivity between each 2 endpoints. The macvtap device will put the virtual interfaces in separate MAC-based VLAN's, isolated from the host.

The macvtap device can function in three different modes: **vepa**, **bridge** and **private** - libvirt supports all three of them. In order to configure networking using a macvtap device, the type attribute of the interface is set to "direct" which can be seen in the following XML example:

```
<domain type='lxc'>
  [ ... ]
    <devices>
    [ ... ]
    <interface type="direct">
      <source dev="p7p1" mode="vepa" />
    </interface>
  </devices>
</domain>
```

In the above example, **p7p1** is a physical network interface on the host. The **mode** tag specifies the mode of the macvtap device - and it can be one of the following:

- **vepa** (Virtual Ethernet Port Aggregator) - in this mode, which is the default, data between endpoints on the same lower device are sent via the lower device (physical Ethernet card), to the physical switch the lower device is connected to. This mode requires that the switch supports *Reflective Relay* mode, also known as *Hairpin* mode. Reflective Relay means that the switch can send back a frame on the same port it received it on. The reason this mode exists is to leverage the switching computation to an external switch (and thus freeing the host).
- **bridge** - in this mode, the endpoints can communicate directly without sending the data out via the lower device. There is no isolation between endpoints on the same lower device, but there is isolation between them and the lower device itself.
- **private** - the nodes on the same Macvtap device can never talk to each other. This is used when you want to isolate the virtual machines connected to the endpoints from each other, but not from the outside network.

11.3.3.2.4.4 Direct Assignment

This options enables a container to have private access to a host interface directly. It is similar to the **lxc-phys** networking configuration option. Technically, this option will move a host network interface from the host network namespace to the container's. Once the container is stopped (destroyed), the interface will be assigned back to the host network namespace. While the container is running, the interface will not be available from the host.

XML Description of the Interface

Assuming the host has interface **fm2-gb0**, this is the XML snippet that assigns it to the container:

```
<domain type='lxc'>
  [ ... ]
  <devices>
    [ ... ]
```

```
    <hostdev mode='capabilities' type='net'>
      <source>
        <interface>fm2-gb0</interface>
      </source>
    </hostdev>
  </devices>
</domain>
```

Guest Configuration and Testing

Once the container is started, the inteface must be configured with IP, netmask, etc. Then it can be used just like it would have been on the host.

```
~ # ifconfig fm2-gb0
fm2-gb0   Link encap:Ethernet  HWaddr 00:04:9f:00:02:05
          BROADCAST MULTICAST  MTU:1500  Metric:1
          RX packets:18 errors:0 dropped:0 overruns:0 frame:0
          TX packets:56 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:1094 (1.0 KiB)  TX bytes:4068 (3.9 KiB)
          Memory:fe5e0000-fe5e0fff

~ # ifconfig fm2-gb0 20.0.0.3 netmask 255.0.0.0
~ # ping -c 3 20.0.0.1
PING 20.0.0.1 (20.0.0.1) 56(84) bytes of data.
64 bytes from 20.0.0.1: icmp_req=1 ttl=64 time=0.377 ms
64 bytes from 20.0.0.1: icmp_req=2 ttl=64 time=0.186 ms
64 bytes from 20.0.0.1: icmp_req=3 ttl=64 time=0.198 ms

--- 20.0.0.1 ping statistics ---
3 packets transmitted, 3 received, 0% packet loss, time 1998ms
rtt min/avg/max/mdev = 0.186/0.253/0.377/0.089 ms
~ #
```

When returning to the host network namespace, the interface loses its configuration and it is down.

11.3.3.2.4.5 VLAN

Libvirt does not directly provide VLAN configuration support-- there is no equivalent to the capability in user space LXC where a container can be configured to have a specific VLAN assigned only to itself (see LXC: How to configure networking using a VLAN (lxc-vlan.conf) on page 2451.

Libvirt containers does not offer equivalent support, but VLANs can be used with libvirt containers using traditional VLAN tools such as vconfig, and the **bridge** or **macvtap** network sharing modes.

This leads to the following different configuration scenarios for using VLAN based network interfaces:

1. Configuring a VLAN on the host:

   ```
   vconfig add eth0 2
   ifconfig eth0.2 192.168.20.2
   ```

   then exposing the **eth0.2** sub-interface in the containers, using **bridging** or direct attachment through a **macvtap** device. These would provide the same functionality as if **eth0.2** were a normal physical interface on the host, but it will only provide connectivity inside the VLAN.

2. Configuring VLAN in container shared with macvtap - in this scenario we assume that the domain has been configured to attach directly to the eth0 interface, and we create the VLAN inside the container. Note that this scenario works only if eth0 does not have a sub-interface in the same VLAN defined on the host. As stated in the Macvtap section, ping will work only between virtual endpoints and the outside network.

3. Configuring VLAN in container shared with bridge - in this scenario we assume that the domain has been configured to attach to a host bridge. This bridge previously had a physical interface attached to it. When starting the domain, virtual endpoints will be created and attached to this bridge inside the domain. We create the VLAN sub-interfaces inside the created containers. Note that this scenario works only if there has not been configured a sub-interface on the physical interface with the same VLAN id.

11.4 Linux Containers (LXC) for NXP QorIQ User's Guide

11.4.1 Introduction to Linux Containers

11.4.1.1 NXP LXC Release Notes

This document describes current limitations in the release of LXC for NXP SoCs.

```
Copyright (C) 2015 NXP Semiconductors, Inc.

NXP LXC Release Notes
04/27/2016

Overview
--------
This document describes new features, current limitations, and
working demos in Linux Containers (LXC) for NXP QorIQ SDK 2.0.

Fixes
-----
  o Seccomp support on ARMv8 platforms.

  o Unprivileged containers support on ARMv8 platforms.

SDK Demo List
-----
  o Basic container usage flow and management commands
  o Container networking setups
       o Shared networking
       o Private NICs
       o Ethernet bridge
       o MACVLAN
       o VLAN
  o Adjusting container capabilities
  o Tuning container resource usage
  o Running application containers
  o Isolating USDPAA applications in LXC containers. This has been
    tested using the USDPAA reflector app in a Multiple Instance Scenario
    on a DPAA board. After parititioning the board resources in order to
    support multiple reflector instances, these have been further isolated
    in container environments.
  o Running an unprivileged container linked to a host bridge.
  o Running containers with Seccomp protection.
```

11.4.1.2 Overview

This document is a guide and tutorial to using Linux Containers on NXP e500-based, ARMv7 and ARMv8-based SoCs.

Linux Containers is a lightweight virtualization technology that allows the creation of environments in Linux called "**containers**" in which Linux applications can be run in isolation from the rest of the system and with fine grained control over resources allocated to the container (e.g. CPU, memory, network).

There are 2 implementations of containers in the QorIQ SDK:

- LXC. LXC is a user space package that provides a set of commands to create and manage containers and uses existing Linux kernel features to accomplish the desired isolation and control.
- Libvirt. The libvirt package is a virtualization toolkit that provides a set of management tools for managing virtual machines and Linux containers. See the ***Libvirt Users Guide*** chapter for general information regarding libvirt. The libvirt driver for containers is called "lxc", but the libvirt "lxc" driver is distinct from the user space LXC package.

Applications in a container run in a "sandbox" and can be restricted in what they can do and what visibility they have. In a container:

- An application "sees" only other processes that are in the container.
- An application has access only to network resources granted to the container.
- If configured as such, an application "sees" only a container-specific root filesystem. In addition to limiting access to data in the system's host rootfs, by limiting the */dev* entries that exist in the containers rootfs this limits the devices that the container can access.
- The file POSIX capabilities available to programs are controlled and configured by the system administrator.
- The container's processes run in what is known as a "control group" which the system administrator can use to monitor and control the container's resources.

Why are containers useful? Below are a few examples of container use cases:

- **Application partitioning** -- control CPU utilization between high priority and low priority applications, control what resources applications can access.
- **Virtual private server** -- boot multiple instances of user space, each which effectively looks like a private instance of a server. This approach is commonly used in website infrastructure.
- **Software upgrade** -- run Linux user space in a container, when it becomes necessary to upgrade applications in the system, create and test upgraded software in a new container. The old container can be stopped and the new container can be started as desired.
- **Terminal servers** -- user accesses the system with a thin client, with containers on the server providing applications. Each user gets a private, sandboxed workspace.

There are two general usage models for containers:

- **application containers**: Running a single application in a container. In this scenario, a single executable program is started in the container.
- **system containers**: Booting an instance of user space in a container. Booting multiple system containers allows multiple isolated instances of user space to run at the same time.

Containers are conceptually different than virtual machine technologies such as QEMU/KVM. Virtual machines emulate a hardware platform and are capable of booting an operating system kernel. A container is a mechanism to isolate Linux applications. In a system using containers there is only one Linux kernel running -- the host Linux kernel.

11.4.1.3 Comparing LXC and Libvirt

LXC and the lxc driver in libvirt provide similar capabilities and use the same kernel mechanisms to create containers. This section highlights some of the differences between the two tools.

LXC

- Container management is done with local LXC package commands. No remote support.

- Container creation done with **lxc-create**. LXC config file and template govern the creation of the template and the container's rootfs.

libvirt

- libvirt abstracts the container and thus a variety of tools can be used to manage containers.
- Remote management is supported.
- Container configuration defined in libvirt XML file.
- No tools to facilitate container creation.
- Same tools can be used to manage containers and KVM/QEMU virtual machines.

11.4.1.4 For Further Information

Linux containers is an approach to virtualization similar to OS virtualization solutions such as Linux VServer and OpenVZ that are widely used for virtual private servers. Documentation for these projects has helpful and relevant information:

- http://linux-vserver.org/Overview
- http://wiki.openvz.org/Main_Page

The LXC package is an open source project and much information is available online.

See the chapter ***Libvirt Users Guide*** for general information about libvirt.

Containers and Security

If using containers to sandbox untrusted applications, a thorough understanding is needed of the capabilities granted to a container and the security vulnerabilities they may imply. The following references are helpful for understanding container security:

- Ubuntu's security issues and mitigations with LXC, https://wiki.ubuntu.com/LxcSecurity
- Emeric Nasi, Exploiting capabilities, http://www.sevagas.com/IMG/pdf/exploiting_capabilities_the_dark_side.pdf
- Secure containers with SELinux and Smack, http://www.ibm.com/developerworks/linux/library/l-lxc-security/index.html
- Seccomp and sandboxing, http://lwn.net/Articles/332974/

Mailing Lists

For LXC, there are two mailing lists available which can be subscribed to. Archives of the lists are also available.

```
https://lists.linuxcontainers.org/listinfo/lxc-devel
```

```
https://lists.linuxcontainers.org/listinfo/lxc-users
```

11.4.2 LXC: Build, Installation, Configuration

11.4.2.1 Summary

To prepare a root filesystem with the needed components for using LXC-based or libvirt containers the following steps are required:

1. Build and include the LXC and/or libvirt packages in the rootfs. For LXC see: LXC: Building with Yocto on page 2433). For libvirt see the chapter ***Libvirt Users Guide*** .
2. Update the Linux kernel configuration and build to included features needed to support containers (see Building the Linux Kernel on page 2433).
3. Update the rootfs so the system is ready to support containers (see Host Root Filesystem Configuration for Linux Containers on page 2436).

11.4.2.2 LXC: Building with Yocto

LXC is a Linux user space package that can easily be added to a rootfs using the Yocto build system.

In the NXP SDK, LXC and all pre-requisite user space packages are included when building the "full" and "virt" image types:

```
bitbake fsl-image-full
bitbake fsl-image-virt
```

LXC can be easily added to any rootfs image by updating the IMAGE_INSTALL_append variable in the **conf/local.conf** file in the Yocto build environment. For example, append the following line to **local.conf**:

```
IMAGE_INSTALL_append = " lxc"
```

If you are building for ARM64 platforms, you need to perform an additional step. You need to update the rootfs target in the board image - by default it is fsl-image-core. If you plan to update this rootfs to, say, fsl-image-virt, you need to add the following line in to build_<machine_release>/conf/local.conf:

```
ROOTFS_IMAGE = "fsl-image-virt”
```

After enabling the required Linux options mentioned in the following chapter, generate the kernel itb:

```
bitbake fsl-image-kernelitb
```

11.4.2.3 Building the Linux Kernel

In order to use LXC the Linux kernel must be configured with options to enable cgroups, namespaces, POSIX file capabilities, and options to support networking in containers.

These options can be enabled automatically by building the Linux kernel with an additional config fragment. In order to do this, add the following line in the **conf/local.conf** file in the Yocto build environment:

```
DELTA_KERNEL_DEFCONFIG_append = " <sdk-devel>/sources/meta-freescale/recipes-kernel/linux/files/
```

```
containers.config"
```

Alternatively, you can enable the options manually. To configure and build the Linux kernel:

```
bitbake virtual/kernel -c cleansstate
bitbake virtual/kernel -c menuconfig
bitbake virtual/kernel
```

Make sure the following configuration options are enabled:

Kernel Configuration Options	Description
General setup ---> [*] Control Group support --> [*] Example debug cgroup subsystem [*] Freezer cgroup subsystem [*] Device controller for cgroups [*] Cpuset support [*] Simple CPU accounting cgroup subsystem [*] Resource counters [*] Memory Resource Controller for Control Groups [*] Memory Resource Controller Swap Extension [*] Memory Resource Controller Swap Extension enabled by default (NEW) [*] Memory Resource Controller Kernel Memory accounting (EXPERIMENTAL) [*] HugeTLB Resource Controller for Control Groups [*] Enable perf_event per-cpu per-container group (cgroup) monitoring [*] Group CPU scheduler [*] Block IO controller	Control Group settings

Kernel Configuration Options	Description
General setup ---> [*] Namespaces support --->[*] UTS namespace [*] IPC namespace [*] User namespace [*] PID Namespaces [*] Network namespace	Namespaces settings

Kernel Configuration Options	Description
Device Drivers --->[*] Network device support --->[*] MAC-VLAN support (EXPERIMENTAL)	Network Device Drivers settings

Kernel Configuration Options	Description
<*> MAC-VLAN based tap driver (EXPERIMENTAL) <*> Virtual ethernet pair device	

Kernel Configuration Options	Description
Device Drivers ---> [*] Character devices ---> [*] Unix98 PTY support [*] Support multiple instances of devpts	Character Device Drivers settings

Kernel Configuration Options	Description
[*] Networking support ---> Networking options ---> <*> 802.1d Ethernet Bridging [*] IGMP/MLD snooping (NEW) <*> 802.1Q VLAN Support [*] GVRP (GARP VLAN Registration Protocol) support	Networking support settings

Kernel Configuration Options	Description
File systems ---> <*> Second extended fs support [*] Ext2 extended attributes [*] Ext2 POSIX Access Control Lists [*] Ext2 Security Labels <*> Ext3 journalling file system support [*] Ext3 extended attributes [*] Ext3 POSIX Access Control Lists [*] Ext3 Security Labels <*> The Extended 4 (ext4) filesystem [*] Ext4 POSIX Access Control Lists [*] Ext4 Security Labels	File System settings

Kernel Configuration Options	Description
[*] Enable the block layer ---> [*] Block layer bio throttling support IO Schedulers ---> <*> CFQ I/O scheduler> [*] CFQ Group Scheduling support	Block layer settings

Kernel Configuration Options	Description
`Kernel Features --->` `[*] Enable seccomp to safely compute untrusted bytecode`	Seccomp kernel support

11.4.2.4 Host Root Filesystem Configuration for Linux Containers

In order to use containers, mount the 'cgroup' pseudo-filesystem. When booting kernels compiled with cgroups support, there is a default directory for mounting them - /sys/fs/cgroup. If they are not already mounted, we will use this to mount our cgroup controllers.

```
mount -t cgroup cgroups /sys/fs/cgroup
```

11.4.3 More Details

11.4.3.1 LXC: Command Reference

This section contains links to available open source documentation for the commands in the LXC user space package.

For a description of the libvirt commands for managing containers see the chapter **Libvirt Users Guide**.

Table 593.

LXC man page	Description	Man Page Link
lxc	lxc overview	click here
lxc-attach	start a process inside a running container	click here
lxc-autostart	start/stop/kill auto-started containers	click here
lxc-cgroup	manage the control group associated with a container	click here
lxc-checkconfig	check the current kernel for lxc support	click here
lxc-clone	clone a new container from an existing one	click here
lxc-config	query LXC system configuration	click here
lxc.conf	a description of all configuration options available	LXC Configuration File Reference on page 2470
lxc-console	launch a console for the specified container	click here
lxc-create	creates a container	click here
lxc-destroy	destroy a container previously created with lxc-create	click here
lxc-execute	run the specified command inside a container	click here
lxc-freeze	freeze (suspend) all the container's processes	click here
lxc-info	query information about a container	click here
lxc-ls	list the containers existing on the system	click here

Table continues on the next page...

Table 593. (continued)

LXC man page	Description	Man Page Link
lxc-monitor	monitor the container state	click here
lxc-snapshot	snapshot an existing container	click here
lxc-start	starts a container previously created with lxc-create	click here
lxc-stop	stop a container	click here
lxc-unfreeze	resumes a containers processes suspended previously with lxc-freeze	click here
lxc-unshare	run a task in a new set of namespaces	click here
lxc-usernsexec	run task as root in a new user namespace	click here
lxc-wait	wait for a specific container state	click here

The following LXC commands are not supported:

- lxc-usernsexec

11.4.3.2 LXC: Configuration Files

NOTE

This section is applicable to LXC only, not to libvirt.

For LXC, configuration files are used to configure aspects of a container at the time it is created. The configuration file defines what resources are private to the container and what is shared. By default the following resources are private to a container:

- process IDs
- sysv ipc mechanisms
- mount points

This means for example, that by default the container will share network resources and the filesystem with the host system, but will have it's own private process IDs.

The container configuration file allows additional isolation to be specified through configuration in the following areas:

- network
- console
- mount points and the backing store for the root filesystem
- control groups (cgroups)
- POSIX capabilities

See the LXC Configuration File Reference on page 2470 for details on each configuration option.

When a container is created a new directory with the container's name is created in /var/lib/lxc. The configuration file for the container is stored in:

```
/var/lib/lxc/[container-name]/config
```

Below is an example of the contents of a minimal configuration file for a container named "foo", which has no networking:

```
$ cat /var/lib/lxc/foo/config
# Container with non-virtualized network
lxc.utsname = foo
```

```
lxc.tty = 1
lxc.pts = 1
lxc.rootfs = /var/lib/lxc/foo/rootfs
lxc.mount.entry=/lib /var/lib/lxc/foo/rootfs/lib none ro,bind 0 0
lxc.mount.entry=/usr/lib /var/lib/lxc/foo/rootfs/usr/lib none ro,bind 0 0
```

See the LXC: Getting Started (with a Busybox System Container) on page 2442 how-to article for an introduction to the container lifecycle and how configuration files are used when creating containers.

Several example configuration files are provided with LXC:

```
/usr/share/doc/lxc/examples/lxc-empty-netns.conf
/usr/share/doc/lxc/examples/lxc-complex.conf
/usr/share/doc/lxc/examples/lxc-no-netns.conf
/usr/share/doc/lxc/examples/lxc-vlan.conf
/usr/share/doc/lxc/examples/lxc-macvlan.conf
/usr/share/doc/lxc/examples/lxc-veth.conf
/usr/share/doc/lxc/examples/lxc-phys.conf
```

11.4.3.3 LXC: Templates

NOTE

This section is applicable to LXC only, not to libvirt.

For LXC, When a container is "created" a directory for the container (which has the same name as the container) is created under /var/lib/lxc. This is where the container's configuration file is stored and can be edited.

For system containers (containers created with **lxc-create**), the default is for the root filesystem structure of the container to be stored here as well.

Creating containers is simplified by the use of example "templates" provided with the LXC. Template examples are provided for a number of different Linux distributions. A template is a script invoked by **lxc-create** that creates the root filesystem structure and sets up the container's config file.

The following example templates are provided with LXC and can be referred to for the expected template structure:

```
/usr/share/lxc/templates/lxc-alpine
/usr/share/lxc/templates/lxc-altlinux
/usr/share/lxc/templates/lxc-archlinux
/usr/share/lxc/templates/lxc-busybox
/usr/share/lxc/templates/lxc-centos
/usr/share/lxc/templates/lxc-cirros
/usr/share/lxc/templates/lxc-debian
/usr/share/lxc/templates/lxc-download
/usr/share/lxc/templates/lxc-fedora
/usr/share/lxc/templates/lxc-gentoo
/usr/share/lxc/templates/lxc-openmandriva
/usr/share/lxc/templates/lxc-opensuse
/usr/share/lxc/templates/lxc-oracle
/usr/share/lxc/templates/lxc-plamo
/usr/share/lxc/templates/lxc-sshd
/usr/share/lxc/templates/lxc-ubuntu
/usr/share/lxc/templates/lxc-ubuntu-cloud
```

For the NXP Linux SDK for QorIQ the busybox template is recommended and has been tested with Yocto-created root filesystems.

The how-to examples provided in this user guide that create system containers use the busybox template.

11.4.3.4 Containers with Libvirt

This section provides an overview to using libvirt-based containers.

For an general introduction to libvirt, please see the chapter ***Libvirt Users Guide***. Also, see the container information available on the libvirt website: http://libvirt.org/drvlxc.html.

With libvirt, a container "domain" is specified in an XML file. The XML is used to "define" the container, which then allows the container to be managed with the standard libvirt domain lifecycle.

Libvirt XML

The XML for the simplest functional container would look like the example below:

```
<domain type='lxc'>
  <name>container1</name>
  <memory>500000</memory>
  <os>
    <type>exe</type>
    <init>/bin/sh</init>
  </os>
  <devices>
    <console type='pty'/>
  </devices>
</domain>
```

Refer to the XML reference information available on the libvirt website for detailed reference information: http://libvirt.org/formatdomain.html

The <domain> element must specify a type attribute of "lxc" for a container/lxc domain. There are 4 additional sub-nodes required:

- <name> - specifies the name of the container
- <memory> - specifies the maximum memory the container may use
- <os> - identifies the initial program to run. In the example this is /bin/sh. For an application based container this is the name of the application. If booting an instance of Linux user space this would typically by /sbin/init.
- <devices> - specifies any devices, in the above example there is just a console

To see a working example using this XML, see the how to article: Basic Example on page 2421.

Filesystem mounts (from http://libvirt.org/drvlxc.html)

In the absence of any explicit configuration, the container will inherit the host OS filesystem mounts. A number of mount points will be made read only, or re-mounted with new instances to provide container specific data. The following special mounts are setup by libvirt:

- /dev a new "tmpfs" pre-populated with authorized device nodes
- /dev/pts a new private "devpts" instance for console devices
- /sys the host "sysfs" instance remounted read-only
- /proc a new instance of the "proc" filesystem
- /proc/sys the host "/proc/sys" bind-mounted read-only
- /sys/fs/selinux the host "selinux" instance remounted read-only
- /sys/fs/cgroup/NNNN the host cgroups controllers bind-mounted to only expose the sub-tree associated with the container
- /proc/meminfo a FUSE backed file reflecting memory limits of the container

Additional filesystem mounts can be created using the <filesystem> node under the <devices> node. See the libvirt.org documentation referenced above for further details.

Device nodes from http://libvirt.org/drvlxc.html

The container init process will be started with CAP_MKNOD capability removed and blocked from re-acquiring it. As such it will not be able to create any device nodes in /dev or anywhere else in its filesystems. Libvirt itself will take care of pre-populating the /dev filesystem with any devices that the container is authorized to use. The current devices that will be made available to all containers are:

- /dev/zero
- /dev/null
- /dev/full
- /dev/random
- /dev/urandom
- /dev/stdin symlinked to /proc/self/fd/0
- /dev/stdout symlinked to /proc/self/fd/1
- /dev/stderr symlinked to /proc/self/fd/2
- /dev/fd symlinked to /proc/self/fd
- /dev/ptmx symlinked to /dev/pts/ptmx
- /dev/console symlinked to /dev/pts/0

11.4.3.5 Linux Control Groups (cgroups)

Linux control groups (or cgroups) is a feature of the Linux kernel that allows the allocation, prioritization,control, and monitoring of resources such as CPU time, memory, network bandwidth among groups of Linux processes.

Cgroups is one of the underlying Linux kernel features that LXC is built upon. LXC automatically creates a cgroup for each container when it is started. A pre-requisite for using LXC is mounting the cgroup virtual filesystem. Mounting the cgroup filesystem is presented in section Host Root Filesystem Configuration for Linux Containers on page 2436.

Cgroups encompass a number of different subsystems or "controllers" that are used for managing and controlling different resources. The following subsystems/controllers are supported:

- cpu - controls CPU allocation for tasks in a cgroup;
- cpuset - assigns individual CPUs and memory nodes to tasks in a cgroup;
- cpuacct - generates automatic reports on CPU resources used by the tasks in a cgroup;
- memory - isolates the memory behavior of a group of tasks from the rest of the system;
- devices - allows or denies access to devices by tasks in a crgroup;
- freezer - suspends or resumes tasks in a cgroup;
- net_cls - tags packets with a class identifier that allows the Linux traffic controller to identify packets originating from a particular cgroup;
- net_prio - provides a way to dynamically set the priority of network traffic per each network interface for applications within various cgroups;
- blkio - controls and monitors access to I/O on block devices by tasks in cgroups.

For an overview of cgoups, see the Linux kernel documentation overview here: Documentation/cgroups/cgroups.txt on page 2486.

You may also check out the Red Hat documentation on cgroups here: https://access.redhat.com/site/documentation/en-US/Red_Hat_Enterprise_Linux/6/html/Resource_Management_Guide/ch-Subsystems_and_Tunable_Parameters.html.

Cgroup subsystems can be configured within the configuration file used when creating a container. The configuration file accepts cgroup configuration in the following form:

```
lxc.cgroup.[subsystem name] = <value>
```

See the LXC Configuration File Reference on page 2470 for further details.

Cgroup subsystems can also be displayed or updated while a container is running using the **lxc-cgroup** command:

```
lxc-cgroup -n [container-name] [cgroup-subsystem] [value]
```

For some examples of how to use cgroups to control container configuration, see the article: LXC: How to use cgroups to manage and control a containers resources on page 2454.

11.4.3.6 Linux Namespaces

Linux namespaces is a feature in the Linux kernel that allows one to unshare and isolate a processes' resources like UTS, PID, IPC, file system mount and network from their parent. To achieve this the kernel places the resources in different namespaces.

When LXC spawns the container's main process it unshares all these resources except the network. The network is controlled from the configuration file and is shared by default.

A network namespace provides an isolated view of the networking stack (network device interfaces, IPv4 and IPv6 protocol stacks, IP routing tables, firewall rules, the /proc/net and /sys/class/net directory trees, sockets, etc.). A physical network device can live in exactly one network namespace. A virtual network device ("veth") pair provides a pipe-like abstraction that can be used to create tunnels between network namespaces, and can be used to create a bridge to a physical network device in another namespace. When a network namespace is freed (i.e., when the last process in the namespace terminates), its physical network devices are moved back to the initial network namespace (not to the parent of the process).

Each namespace is documented in the Linux **clone** man page. See: clone (2)

11.4.3.7 POSIX Capabilities

Linux supports the concept of file "capabilities" which provides fine grained control over what executable programs are permitted to do. Instead of the "all or nothing" paradigm where a super-user or "root" has the power to perform all operations, capabilities provide a mechanism to grant a specific program specific capabilities.

LXC uses this feature of the kernel to implement containers. By default processes running in a container will have **all** capabilities, but this can be configured. Capabilities can be dropped in the container's configuration file. See LXC: Configuration Files on page 2437.

For example, to drop the CAP_SYS_MODULE, CAP_MKNOD, CAP_SETUID, and CAP_NET_RAW capabilities, the following configuration file options would be specified:

```
lxc.cap.drop = sys_module mknod setuid net_raw
```

Each capability is documented in the Linux **capabilities** man page. See: capabilities (7)

In order to fully isolate a container, the capabilities to be dropped must be carefully considered. The Linux Vserver project considers only the following capabilities as **safe** for virtual private servers:

```
CAP_CHOWN
CAP_DAC_OVERRIDE
CAP_DAC_READ_SEARCH
```

```
    CAP_FOWNER
    CAP_FSETID
    CAP_KILL
    CAP_SETGID
    CAP_SETUID
    CAP_NET_BIND_SERVICE
    CAP_SYS_CHROOT
    CAP_SYS_PTRACE
    CAP_SYS_BOOT
    CAP_SYS_TTY_CONFIG
    CAP_LEASE
```

(see: http://linux-vserver.org/Paper#Secure_Capabilities)

11.4.4 LXC: How To's

11.4.4.1 LXC: Getting Started (with a Busybox System Container)

The following article describes steps to run a simple container example. All the command below are issued from a host Linux command prompt.

1. Confirm that your kernel environment is configured correctly using **lxc-checkconfig**. All options should show as 'enabled.

```
# lxc-checkconfig
--- Namespaces ---
Namespaces: enabled
Utsname namespace: enabled
Ipc namespace: enabled
Pid namespace: enabled
User namespace: missing
Network namespace: enabled
Multiple /dev/pts instances: enabled

--- Control groups ---
Cgroup: enabled
Cgroup clone_children flag: enabled
Cgroup device: enabled
Cgroup sched: enabled
Cgroup cpu account: enabled
Cgroup memory controller: enabled
Cgroup cpuset: enabled

--- Misc ---
Veth pair device: enabled
Macvlan: enabled
Vlan: enabled
File capabilities: enabled

Note : Before booting a new kernel, you can check its configuration
usage : CONFIG=/path/to/config /usr/bin/lxc-checkconfig
```

If the cgroup namespace option shows as required:

```
Cgroup namespace: required
```

...most likely the /cgroup directory needs to be created and or mounted. See Host Root Filesystem Configuration for Linux Containers on page 2436.

NOTE: the User namespace is reported as missing. Although initial support for User Namespaces has been enabled in Linux 3.8, a lot of work still had to be done after this release and the USER_NS config flag could not be enabled. This has no impact on the functionality of containers, since User namespace support was not implemented - just the flag was there.

2. Create a container

   Create a system container using lxc-create and specify the busybox template and lxc-empty-netns.conf config file. lxc-empty-netns.conf is a simple config file with no networking:

```
# lxc-create -n foo -t busybox -f /usr/share/doc/lxc/examples/lxc-empty-netns.conf
setting root password to "root"
Password for 'root' changed
#
```

   By default, LXC will try to install the dropbear ssh utility, if it's available on the host system. The Busybox template also has support for installing OpenSSH (assuming it's installed on the host Linux) in the container. This needs to be passed explicitly using a command line parameter:

```
# lxc-create -n foo -t busybox -f /usr/share/doc/lxc/examples/lxc-empty-netns.conf -- -s openssh
setting root password to "root"
Password for 'root' changed
'OpenSSH' ssh utility installed
#
```

3. List containers that exist

```
# lxc-ls -l
drwxr-xr-x 3 root root 1024 May 30 15:37 foo
```

4. From a shell on the host Linux, start the container. When prompted, press 'Enter'.

```
# lxc-start -n foo -F

Please press Enter to activate this console.

/ #

/ #
```

   Note that the shell is now running within the container. Normal Linux commands can be executed.

   Important notice: while this mode starts the container and directly connects to one of its terminals, there is a minor caveat: the terminal will be stuck in this container console until the container is halted (either from here, by running **halt**, or from another terminal by running **lxc-stop**). In order to avoid this, there is also the possibility to start the container as a daemon and connect to it using **lxc-console** (this is the default mode). This provides better terminal capabilities and the user is not forced to stop the container from another terminal. On the other hand, there is no indication that after running **lxc-start** the container has actually started - no errors are reported. You must check if the container is running yourself, using **lxc-info** - see below.

```
# lxc-start -n foo
# lxc-console -n foo

Type <Ctrl+a q> to exit the console, <Ctrl+a Ctrl+a> to enter Ctrl+a itself

foo login: root
Password: (root)
~ #
~ #
```

```
~ #
~ # (Ctrl+a q)
#
```

This will be the preferred mode of starting and connecting to containers.

5. List processes in the container.

   From in the container shell use the ps command to list processes:

```
~ # ps
  PID USER       VSZ STAT COMMAND
    1 root      2384 S    init
    4 root      2384 S    /bin/syslogd
    6 root      2388 S    -sh
    7 root      2384 S    init
    8 root      2388 R    ps
```

   Note process IDs have a number-space unique to the container.

6. Show the status of the foo container (from a host shell):

```
# lxc-info -n foo
Name:           foo
State:          RUNNING
PID:            4544
CPU use:        0.01 seconds
Memory use:     472.00 KiB
KMem use:       0 bytes
```

7. Look at the files/directories in /var/lib/lxc related to the container

```
# ls -l /var/lib/lxc/foo
total 2
-rw-r--r--  1 root root  675 May 30 15:37 config
drwxr-xr-x 16 root root 1024 May 30 15:44 rootfs
```

   This shows the containers config file and rootfs backing store.

   Look at the contents of the config file:

```
# cat /var/lib/lxc/foo/config
# Template used to create this container: /usr/share/lxc/templates/lxc-busybox
# Parameters passed to the template:
# For additional config options, please look at lxc.conf(5)
lxc.utsname = omega
lxc.network.type = empty
lxc.network.flags = up
lxc.rootfs = /var/lib/lxc/foo/rootfs
lxc.haltsignal = SIGUSR1
lxc.utsname = foo
lxc.tty = 1
lxc.pts = 1
lxc.cap.drop = sys_module mac_admin mac_override sys_time

# When using LXC with apparmor, uncomment the next line to run unconfined:
#lxc.aa_profile = unconfined
lxc.mount.entry = /lib lib none ro,bind 0 0
lxc.mount.entry = /usr/lib usr/lib none ro,bind 0 0
```

```
lxc.mount.entry = /sys/kernel/security sys/kernel/security none ro,bind,optional 0 0
lxc.mount.auto = proc:mixed sys
```

8. Start a process inside the container using lxc-attach. This command will run the process inside the system container's isolated environment. The container has to be running already.

```
# lxc-attach -n foo -- /bin/sh
root@foo:/# ps
PID   USER     TIME   COMMAND
    1 root       0:00 init
    6 root       0:00 /bin/syslogd
    8 root       0:00 /bin/getty -L tty1 115200 vt100
    9 root       0:00 init
   10 root       0:00 /bin/sh
   11 root       0:00 ps
root@foo:/# ls -l /dev
total 0
crw-rw-rw-    1 root     5         136,   1 May 26 13:13 console
lrwxrwxrwx    1 root     root             13 May 26 13:12 fd -> /proc/self/fd
lrwxrwxrwx    1 root     root              7 May 26 13:13 kmsg -> console
srw-rw-rw-    1 root     root              0 May 26 13:13 log
crw-rw-rw-    1 root     root        1,    3 May 26 13:10 null
lrwxrwxrwx    1 root     root             13 May 26 13:12 ptmx -> /dev/pts/ptmx
drwxr-xr-x    2 root     root              0 May 26 13:13 pts
brw-------    1 root     root        1,    0 May 26 13:10 ram0
drwxrwxrwt    2 root     root             40 May 26 13:13 shm
lrwxrwxrwx    1 root     root             15 May 26 13:12 stderr -> /proc/self/fd/2
lrwxrwxrwx    1 root     root             15 May 26 13:12 stdin -> /proc/self/fd/0
lrwxrwxrwx    1 root     root             15 May 26 13:12 stdout -> /proc/self/fd/1
crw-rw-rw-    1 root     root        5,    0 May 26 13:10 tty
crw-rw-rw-    1 root     root        4,    0 May 26 13:10 tty0
crw--w----    1 root     root      136,    0 May 26 13:13 tty1
crw-rw-rw-    1 root     root        4,    0 May 26 13:10 tty5
crw-rw-rw-    1 root     root        1,    9 May 26 13:10 urandom
crw-rw-rw-    1 root     root        1,    5 May 26 13:10 zero
root@foo:/#
```

9. Stop the container (from a host shell)

```
# lxc-stop -n foo
#
# lxc-info -n foo
Name:           foo
State:          STOPPED
```

10. Destroy the container. This removes the containers config file and backing store.

```
# lxc-destroy -n foo
#
```

11.4.4.2 LXC: How to configure non-virtualized networking (lxc-no-netns.conf)

One approach to providing networking capability to a container is to simply allow the container to use existing host network interfaces. To accomplish this, a configuration file is created with no networking setup (i.e. the **lxc.network.type** property is not set) and the default will be to allow the container to access the host's networking interfaces.

With this approach no network namespace is created for the container.

An example config is provided:

```
/usr/share/doc/lxc/examples/lxc-no-netns.conf
```

The contents of lxc-no-netns.conf look like this:

```
# Container with non-virtualized network
lxc.network.type = none
lxc.utsname = delta
```

The example below shows starting an application container (running bash) with this config file and shows that the host network interface fm2-mac5 is inherited and accessible by the container:

```
# lxc-execute -n mytest -f /usr/share/doc/lxc/examples/lxc-no-netns.conf -- /bin/bash
bash-4.3# ifconfig
fm2-mac5  Link encap:Ethernet  HWaddr 00:04:9f:02:7a:3b
          inet addr:10.0.0.1  Bcast:10.255.255.255  Mask:255.0.0.0
          inet6 addr: fe80::204:9fff:fe02:7a3b/64 Scope:Link
          UP BROADCAST MULTICAST  MTU:1500  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0

          RX bytes:272 (272.0 B)  TX bytes:272 (272.0 B)
bash-4.2#
```

11.4.4.3 LXC: How to assign a physical network interface to a container (lxc-phys.conf)

One approach to providing networking capability to a container is to directly assign an available, unused network interface to the container. The interface is not shared, it becomes the private resource of the container.

An example LXC configuration file is provided to configure this type of networking:

```
    /usr/share/doc/lxc/examples/lxc-phys.conf
```

The contents of the default lxc-phys.conf example are show below:

```
# Container with network virtualized using a physical network device with name
# 'eth0'
lxc.utsname = gamma
lxc.network.type = phys
lxc.network.flags = up
lxc.network.link = eth0
lxc.network.hwaddr = 4a:49:43:49:79:ff
```

```
lxc.network.ipv4 = 10.2.3.6/24
lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3297
```

Note: The network type is set to: **phys**. Make a copy of the example config file and update it with the name of the Ethernet interface to be assigned, an appropriate IP address, and any other appropriate changes (e.g. mac address). For example, the change (in universal diff format) to set the interface fm2-gb0 and IP address 192.168.10.3 would look like:

```
--- /usr/share/doc/lxc/examples/lxc-phys.conf
+++ lxc-phys.conf
@@ -3,7 +3,6 @@
 lxc.utsname = gamma
 lxc.network.type = phys
 lxc.network.flags = up
-lxc.network.link = eth0
-lxc.network.hwaddr = 4a:49:43:49:79:ff
-lxc.network.ipv4 = 10.2.3.6/24
-lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3297
+lxc.network.link = fm2-mac5
+lxc.network.hwaddr = 00:e0:0c:00:93:05
+lxc.network.ipv4 = 192.168.10.3/24
```

A simple way to test the new config file and the network interface is to run /bin/bash as a command with lxc-execute, which will provide a shell running in the container:

```
# lxc-execute -n mytest -f lxc-phys.conf -- /bin/bash
bash-4.2#
```

In the container, use the fm1-gb4 interface normally:

```
bash-4.3# ifconfig
fm2-mac5  Link encap:Ethernet  HWaddr 00:e0:0c:00:93:05
          inet addr:192.168.10.3  Bcast:192.168.10.255  Mask:255.255.255.0
          UP BROADCAST MULTICAST  MTU:1500  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0
          TX packets:6 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:0 (0.0 B)  TX bytes:508 (508.0 B)
          Memory:fe5e8000-fe5e8fff

lo        Link encap:Local Loopback
          inet addr:127.0.0.1  Mask:255.0.0.0
          inet6 addr: ::1/128 Scope:Host
          UP LOOPBACK RUNNING  MTU:65536  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0
          TX packets:0 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:0
          RX bytes:0 (0.0 B)  TX bytes:0 (0.0 B)

bash-4.2# ping -c 3 192.168.10.1
PING 192.168.10.1 (192.168.10.1) 56(84) bytes of data.

```

11.4.4.4 LXC: How to configure networking with virtual Ethernet pairs (lxc-veth.conf)

One approach to providing a virtual network interface to a container is using the "Virtual ethernet pair device" feature of the Linux kernel in conjunction with a network bridge.

See the veth description in LXC Configuration File Reference on page 2470 for additional details on this approach to networking.

With this approach LXC creates a new network namespace for the container.

The example configuration file lxc-veth.conf demonstrates this approach:

```
/usr/share/doc/lxc/examples/lxc-veth.conf
```

The contents of the default lxc-veth.conf example are show below:

```
# Container with network virtualized using a pre-configured bridge named br0 and
# veth pair virtual network devices
lxc.utsname = beta
lxc.network.type = veth
lxc.network.flags = up
lxc.network.link = br0
lxc.network.hwaddr = 4a:49:43:49:79:bf
lxc.network.ipv4 = 10.2.3.5/24
lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3597
```

Note, the network type value is: **veth** and the link property value is **br0**.

First, create a network bridge which is attached to a physical network interface and assign the bridge an IP address. The bridge becomes one endpoint In the example below the bridge br0 is created, interface fm2-gb1 is added to it, and the bridge is assigned an IP address of 192.168.20.2.

```
# brctl addbr br0
# ifconfig br0 192.168.20.2 up
# ifconfig fm2-mac5 up
# brctl addif br0 fm2-mac5
```

Make a copy of the example config file and update it with an appropriate IP address and any other appropriate changes (e.g. mac address). For example, the change (in universal diff format) to update the IP address to 192.168.20.3 would look like:

```
--- /usr/share/doc/lxc/examples/lxc-veth.conf
+++ lxc-veth.conf
@@ -5,5 +5,5 @@
 lxc.network.flags = up
 lxc.network.link = br0
 lxc.network.hwaddr = 4a:49:43:49:79:bf
-lxc.network.ipv4 = 10.2.3.5/24
+lxc.network.ipv4 = 192.168.20.3/24
 lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3597
```

A simple way to test the new config file and the network interface is to run /bin/bash as a command with lxc-execute, which will provide a shell running in the container:

```
# lxc-execute -n mytest -f lxc-veth.conf -- /bin/bash
bash-4.2#
```

In the container, use the virtual network interface (eth0 in this example) normally:

```
bash-4.2# ifconfig
eth0      Link encap:Ethernet  HWaddr 4a:49:43:49:79:bf
          inet addr:192.168.20.3  Bcast:192.168.20.255  Mask:255.255.255.0
          inet6 addr: fe80::4849:43ff:fe49:79bf/64 Scope:Link
          inet6 addr: 2003:db8:1:0:214:1234:fe0b:3597/64 Scope:Global
          UP BROADCAST RUNNING MULTICAST  MTU:1500  Metric:1
          RX packets:6 errors:0 dropped:0 overruns:0 frame:0

```

11.4.4.5 LXC: How to configure networking with macvlan (lxc-macvlan.conf)

An LXC container can be provided with a virtual network interface using the "MAC-VLAN" feature of the Linux kernel (see kernel config option CONFIG_MACVLAN). MAC-VLAN allows virtual interfaces to be created that route packets to or from a MAC address to a physical network interface.

See the macvlan description in LXC Configuration File Reference on page 2470 for some additional details on this approach to networking.

The example configuration file lxc-veth.conf demonstrates this approach:

```
/usr/share/doc/lxc/examples/lxc-macvlan.conf
```

The contents of the provided lxc-phys.conf example configuration file are show below:

```
# Container with network virtualized using the macvlan device driver
lxc.utsname = alpha
lxc.network.type = macvlan
lxc.network.flags = up
lxc.network.link = eth0
lxc.network.hwaddr = 4a:49:43:49:79:bd
lxc.network.ipv4 = 10.2.3.4/24
lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3596
```

Make a copy of the example config file and update it with the physical network interface to be used, an appropriate IP address, and any other appropriate changes (e.g. mac address). For example, the change (in universal diff format) to specify the fm1-gb4 interface and update the IP address to 192.168.1.24 would look like:

```
--- /usr/share/doc/lxc/examples/lxc-macvlan.conf
+++ lxc-macvlan.conf
@@ -2,7 +2,7 @@
 lxc.utsname = alpha
 lxc.network.type = macvlan
 lxc.network.flags = up
-lxc.network.link = eth0
+lxc.network.link = fm2-mac5
 lxc.network.hwaddr = 4a:49:43:49:79:bd
-lxc.network.ipv4 = 10.2.3.4/24
+lxc.network.ipv4 = 192.168.10.3/24
 lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3596
```

Put the network interface in promiscuous mode:

```
# ifconfig fm2-mac5 promisc
# ifconfig fm2-mac5
fm2-gb0   Link encap:Ethernet  HWaddr 00:e0:0c:00:93:05
          inet addr:192.168.10.2  Bcast:192.168.10.255  Mask:255.255.255.0
          inet6 addr: fe80::2e0:cff:fe00:9305/64 Scope:Link
          UP BROADCAST RUNNING PROMISC MULTICAST  MTU:1500  Metric:1
          RX packets:5 errors:0 dropped:0 overruns:0 frame:0
          TX packets:17 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:344 (344.0 B)  TX bytes:1314 (1.2 KiB)
          Memory:fe5e0000-fe5e0fff
```

Test the MAC-VLAN interface by starting an application container running /bin/bash:

```
# lxc-execute -n mytest -f lxc-macvlan.conf -- /bin/bash
bash-4.2#
```

Note: the shell prompt above ("bash-4.2") is in the container.

Test the interface in the now running container:

```
bash-4.2# ifconfig
eth0      Link encap:Ethernet  HWaddr 4a:49:43:49:79:bd
          inet addr:192.168.10.3  Bcast:192.168.10.255  Mask:255.255.255.0
          inet6 addr: fe80::4849:43ff:fe49:79bd/64 Scope:Link
          inet6 addr: 2003:db8:1:0:214:1234:fe0b:3596/64 Scope:Global
          UP BROADCAST RUNNING MULTICAST  MTU:1500  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0
          TX packets:7 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:0
          RX bytes:0 (0.0 B)  TX bytes:586 (586.0 B)

lo        Link encap:Local Loopback
          inet addr:127.0.0.1  Mask:255.0.0.0
          inet6 addr: ::1/128 Scope:Host
          UP LOOPBACK RUNNING  MTU:65536  Metric:1
          RX packets:0 errors:0 dropped:0 overruns:0 frame:0
          TX packets:0 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:0
```

```
          RX bytes:0 (0.0 B)  TX bytes:0 (0.0 B)

bash-4.2# ping -c 3 192.168.10.1
PING 192.168.10.1 (192.168.10.1) 56(84) bytes of data.
64 bytes from 192.168.10.1: icmp_req=1 ttl=64 time=0.380 ms

```

11.4.4.6 LXC: How to configure networking using a VLAN (lxc-vlan.conf)

A container can be provided with a virtual network interface using VLANs.

See the vlan description in LXC Configuration File Reference on page 2470 for some additional details on this approach to networking.

The example configuration file lxc-veth.conf demonstrates this approach:

```
/usr/share/doc/lxc/examples/lxc-vlan.conf
```

The contents of the provided lxc-vlan.conf example configuration file are show below:

```
 # Container with network virtualized using the vlan device driver
lxc.utsname = alpha
lxc.network.type = vlan
lxc.network.vlan.id = 1234
lxc.network.flags = up
lxc.network.link = eth0
lxc.network.hwaddr = 4a:49:43:49:79:bd
lxc.network.ipv4 = 10.2.3.4/24
lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3596
```

Make a copy of the example config file and update it with the physical network interface to be used and the vlan ID, an appropriate IP address, and any other appropriate changes. For example, the change (in universal diff format) to specify the fm2-gb0 interface, a VLAN id of 2, and an IP address of 192.168.30.2 would look like:

```
--- /usr/share/doc/lxc/examples/lxc-vlan.conf   2013-05-30 14:22:14.980406375 +0300

```

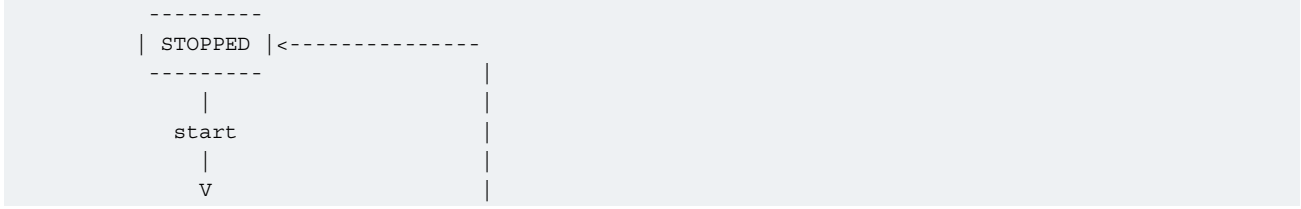
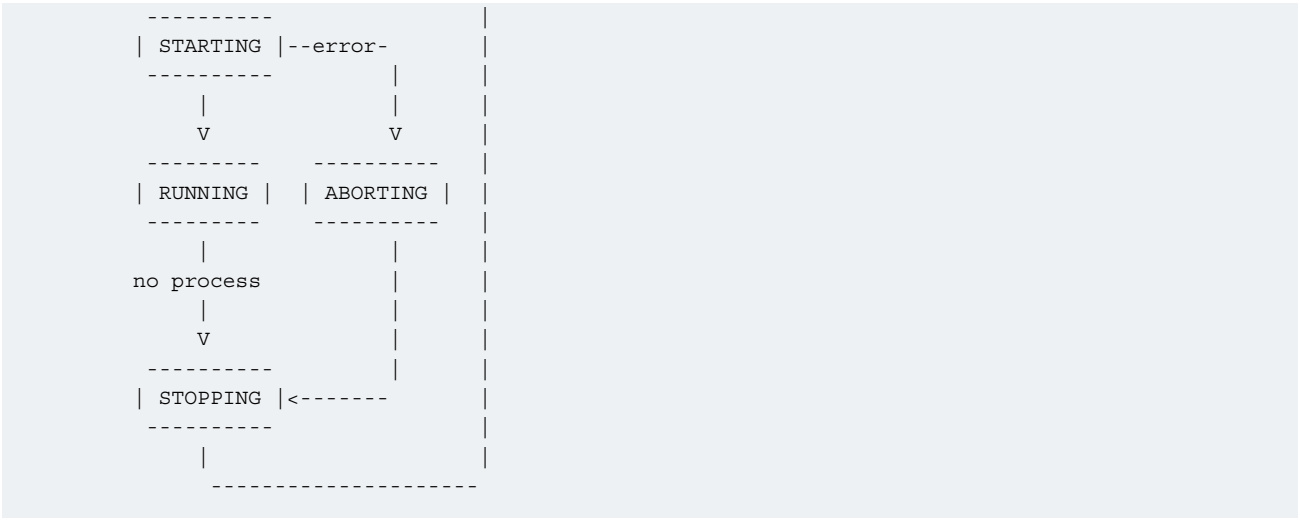
11.4.4.7 LXC: How to monitor containers

Containers transition through a set of well defined states. After a container is created it is in the "stopped" state.





A number of commands are available in LXC to monitor the state of a container. The following examples provide an introduction and demonstrate the capabilities of these commands.

1. lxc-info

   The lxc-info command shows the current state of the container.

   In the example below, a container called "foo" has already been created but not started and the container is stopped:

```
# lxc-info -n foo
Name:           foo
State:          STOPPED
After the container is started lxc-info shows the container in the running state:
```

```
# lxc-start -n foo
# lxc-info -n foo
Name:           foo
State:          RUNNING
PID:            5075
CPU use:        0.01 seconds
Memory use:     508.00 KiB
KMem use:       0 bytes
```

2. lxc-monitor

   The **lxc-monitor** command can monitor the state of one or more containers, the command continues to run until it is killed.

   In this example **lxc-monitor** monitors the state of a container named "foo":

```
# lxc-monitor -n foo
```

   In a separate shell, start and then stop the container foo:

```
# lxc-start -n foo
# lxc-stop -n foo
```

   The running **lxc-monitor** command displays the state changes as they occur:

```
'foo' changed state to [STARTING]
'foo' changed state to [RUNNING]
```

```
'foo' changed state to [STOPPING]
'foo' changed state to [STOPPED]
```

3. lxc-wait

   The lxc-wait command will wait for a container state change and then exit. This can be useful for scripting and synchonizing the start or exit of a container.

   For example, to wait until the container named "foo" stops:

```
# lxc-wait -n foo -s STOPPED
```

11.4.4.8 LXC: How to modify the capabilities of a container to provide additional isolation

As described in POSIX Capabilities on page 2441 ,by default processes running in a container will have all capabilities. And the configuration for a container can further restrict these capabilities.

This example shows how to remove the ability for a container to issue the mknod command.

By default a container can issue the mknod command:

```
~ # mknod zero c 1 5
~ # ls -l zero
crw-r--r--    1 root     root        1,   5 Jun  3 17:08 zero
```

In this example we modify the config file of a container named "foo" (/var/lib/lxc/foo/config) and specify in the **lxc.cap.drop** property that the mknod capability (CAP_MKNOD) should be removed:

```
@@ -5,6 +5,7 @@
 lxc.utsname = foo
 lxc.tty = 1
 lxc.pts = 1
+lxc.cap.drop = mknod
 lxc.rootfs = /var/lib/lxc/foo/rootfs
 lxc.mount.entry=/lib /var/lib/lxc/foo/rootfs/lib none ro,bind 0 0
 lxc.mount.entry=/usr/lib /var/lib/lxc/foo/rootfs/usr/lib none ro,bind 0 0
```

Now restart the container and the mknod operation is no longer permitted:

```
~ # mknod zero c 1 5
mknod: zero: Operation not permitted
```

11.4.4.9 LXC: How to use cgroups to manage and control a containers resources

This example demonstrates how to use control croups to control which CPU's a container is scheduled on and the percentage of CPU time allocated to a container.

In this example we'll examine and change:

- the **cpuset** subsystem's **cpus** parameter which controls which physical CPUs the container's processes will run on
- the **cpu** subsystem's **shares** parameter which controls the percentage of the CPU to be allocated to the container

1. Start two application containers each running /bin/bash:

First container:

```
# lxc-execute -n foo1 -f lxc-no-netns.conf -- /bin/bash
bash-4.2#
```

Second container:

```
# lxc-execute -n foo2 -f lxc-no-netns.conf -- /bin/bash
bash-4.2#
```

2. In both containers start a process that will put a 100% load on the CPUs:

```
(while true; do true; done) &
```

3. The **cpuset.cpus** subsystem/value specifies which physical CPUs the container's processes run on. From a host shell, examine this with the **lxc-cgroup** command:

```
# lxc-cgroup -n foo1 cpuset.cpus
0-7
```

In this example the host system has 4 CPUs.

This can also be seen directly through the /cgroup filesystem:

```
# cat /cgroup/cpuset/lxc/foo1/cpuset.cpus
0-7
```

4. Change both containers to run only on CPU 2:

```
# lxc-cgroup -n foo1 cpuset.cpus 2
# lxc-cgroup -n foo2 cpuset.cpus 2
#
```

The top command now shows CPU 2 with 100% utilization. The bash commands running in each container, each have about 50% of the CPU:

```
top - 17:14:41 up 10 min,  4 users,  load average: 1.64, 0.61, 0.23
Tasks: 100 total,   3 running,  97 sleeping,   0 stopped,   0 zombie
Cpu0  :  0.0%us,  0.3%sy,  0.0%ni, 99.7%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu1  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu2 :100.0%us, 0.0%sy, 0.0%ni, 0.0%id, 0.0%wa, 0.0%hi, 0.0%si, 0.0%st
Cpu3  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu4  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu5  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu6  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Cpu7  :  0.0%us,  0.0%sy,  0.0%ni,100.0%id,  0.0%wa,  0.0%hi,  0.0%si,  0.0%st
Mem:   3996400k total,   189836k used,  3806564k free,     1652k buffers
Swap:        0k total,        0k used,        0k free,    26180k cached

  PID USER      PR  NI  VIRT  RES  SHR S %CPU %MEM    TIME+  COMMAND
 2875 root      20   0  3624  416  164 R   50  0.0   1:28.12 bash
 2874 root      20   0  3624  424  168 R   50  0.0   1:31.06 bash
```

5. The cpu.shares subsystem/value specifies the percentage of the CPU allocated to the cgroup/container. By default each container has a shares value of 1024:

```
# lxc-cgroup -n foo1 cpu.shares
1024
```

```
# lxc-cgroup -n foo2 cpu.shares
1024
```

6. Change container "foo2" to have about 10% of the CPU:

```
# lxc-cgroup -n foo2 cpu.shares 100
# lxc-cgroup -n foo1 cpu.shares 900
```

Now the top command output reflects the new CPU allocation:

```
  PID USER      PR  NI  VIRT  RES  SHR S %CPU %MEM    TIME+  COMMAND
 2874 root      20   0  3624  424  168 R   90  0.0   2:53.63 bash
 2875 root      20   0  3624  416  164 R   10  0.0   2:11.36 bash
```

7. Stop the containers

```
# lxc-stop -n foo1 -k
# lxc-stop -n foo2 -k
#
```

11.4.4.10 LXC: How to run an application in a container with lxc-execute

The **lxc-execute** command allows a single application to be run in a container (as contrasted with a system container which boots an instance of Linux user space starting with System V style init).

In the example below an instance of a QEMU/KVM virtual machine is started in a container called foo.

Note, it is not required to explicitly create (and destroy) a container when running application containers with lxc-execute. The containers will automatically created and destroyed.

1. Start QEMU in the container with lxc-execute:

```
# lxc-execute -n foo -f lxc-no-netns.conf -- qemu-system-ppc -enable-kvm -smp 2 -m 256M -nographic
-M ppce500 -kernel uImage -initrd rootfs.ext2.gz -append "root=/dev/ram rw console=ttyS0,115200" -
serial tcp::4445,server,telnet
```

NOTE: For 64bit platforms, please replace qemu-system-ppc with qemu-system-ppc64.

Some notes:

- The QEMU command line follows the double dash ("--") specfied on the lxc-execute command line and distinguishes argument to lxc-execute from arguments to qemu-system-ppc.
- Using the specified configuration file, QEMU will run in the network namespace of the host system, meaning the TCP ports for serial and the monitor (ports 4445 and 4446) can be accessed from the host. However, lxc-execute will accept a configuration file as an argument allowing customization of the degree of isolation of the container.
- In this example there are 2 virtual cpus specified, which results in a total of 3 QEMU processes/threads. So we expect to see 3 QEMU processes in the container.

2. Examine the state of the container with lxc-ls and lxc-info:

```
# lxc-ls --active
foo

# lxc-info -n foo
Name:           foo
State:          RUNNING
```

```
PID:            3205
IP:             192.168.2.80
CPU use:        3.96 seconds
Memory use:     140.46 MiB
KMem use:       0 bytes
```

3. In the QEMU console look at the CPU status which shows the process IDs for the two virtual CPUs in in the virtual machine:

```
# (qemu) info cpus
* CPU #0: nip=0x00000000c001450c thread_id=4
  CPU #1: nip=0x00000000c001450c thread_id=5
(qemu)
```

Note that the process/thread IDs as viewed from within the container (thread IDs 4 and 5) are different than from the host, since they are in a different namespace.

5. Using the container's cgroup restrict the physical CPUs on which the virtual machine is allowed to run.

By default all 4 CPUs can be used by the container :

```
# by default all 4 CPUs can be used by the container
# cat /cgroup/lxc/foo/cpuset.cpus
0-3
```

Restrict the containers processes to CPUs 2 and 3:

```
# echo 2-3 > /cgroup/lxc/foo/cpuset.cpus
# cat /cgroup/lxc/foo/cpuset.cpus
2-3
```

11.4.4.11 LXC: How to run an unprivileged container

With the addition of the user namespace in the Linux kernel, a normal user on a Linux host can create and run container instances. This feature has been integrated in the LXC package, starting from version 1.0.

The steps below detail the necessary steps required in order to configure and manage an unprivileged container.

NOTE: Before running these steps, make sure that the host is properly configured for container use, by running **lxc-checkconfig** (cgroups, namespaces, etc.). If some of the options are missing, please refer to the guidelines in LXC: Build, Installation, Configuration on page 2433.

1. Create the **/etc/subuid** and **/etc/subgid** file on the Linux host. These will be used to store the unprivileged user's subordinate UIDs and GIDs. The unprivileged user has the ability to manage users on his own in his user namespace, and their IDs will be mapped to corresponding ranges on IDs on the host system. The subordinate IDs will correspond to the ranges defined in these files.

   ```
   for file in '/etc/subuid' '/etc/subgid'; do
       touch $file
       chown root:root $file
       chmod 644 $file
   done
   ```

2. Add a user in the system - **lxc-user**.

   ```
   useradd lxc-user -p $(echo test | openssl passwd -1 -stdin)
   ```

3. Check the contents of **/etc/subuid** and **/etc/subgid**. If they contain the following entries, the user has been automatically assigned a default set of subordinate IDs.

```
root@t4240qds:~# cat /etc/sub*
lxc-user:100000:65536
lxc-user:100000:65536
root@t4240qds:~#
```

   If the files are empty, you need to manually assign a set of subordinate IDs to the user.

```
usermod --add-subuids 100000-165536 lxc-user
usermod --add-subgids 100000-165536 lxc-user
```

4. The container will have a virtual interface linked to a bridge on the host. Use the following command to create the bridge.

```
brctl addbr br0 && ifconfig br0 10.0.0.1
```

5. You must create and edit the **/etc/lxc/lxc-usernet** file. This file specifies how many interfaces the lxc-user will be allowed to have linked in this bridge.

```
echo "lxc-user veth br0 10" > /etc/lxc/lxc-usernet
```

6. Create the **/home/lxc-user/.config/lxc** directory on the host. This will hold the default configuration for unprivileged containers belonging to the lxc-user.

```
mkdir -p /home/lxc-user/.config/lxc
```

7. **Create** the default container configuration file, **/home/lxc-user/.config/lxc/default.conf**, and paste the following lines.

```
lxc.network.type = veth
lxc.network.link = br0
lxc.network.flags = up
lxc.id_map = u 0 100000 65536
lxc.id_map = g 0 100000 65536
```

8. Change the ownership of the newly created files and folders to lxc-user.

```
chown -R lxc-user:lxc-user /home/lxc-user/.config
```

9. For each of the mounted cgroup controllers, created a directory in the top called **lxc-user**, and change its ownership to lxc-user. Be sure to enable the cgroup.clone_children and memory.use_hierarchy flags.

```
echo 1 > /sys/fs/cgroup/memory/memory.use_hierarchy

for c in `ls /sys/fs/cgroup/`; do
    echo 1 > /sys/fs/cgroup/$c/cgroup.clone_children
    mkdir /sys/fs/cgroup/$c/lxc-user
    chown -R lxc-user:lxc-user /sys/fs/cgroup/$c/lxc-user
done
```

10. **Login as the new user in a new console.**

```
t4240qds login: lxc-user
Password:
t4240qds:~$
```

11. Copy the shell PID in the lxc-user cgroups.

```
for c in `ls /sys/fs/cgroup/`; do
    echo $$ > /sys/fs/cgroup/$c/lxc-user/tasks
done
```

12. From the same shell as before, create a Busybox container. You can pass it a custom config file using the **-f** cmdline parameter. Otherwise, it will pick the default config from **/home/lxc-user/.config/default.conf**.

```
t4240qds:~$ lxc-create -n foo -t busybox
setting root password to "root"
Password for 'root' changed
t4240qds:~$
```

13. Start the container.

```
t4240qds:~$ lxc-start -n foo -F

Please press Enter to activate this console.
/ #
/ #
/ # whoami
root
/ #
```

Now you can interact with the container as you would with one created by root. **Make sure that all container commands are run as lxc-user.**

11.4.4.12 LXC: How to run containers with Seccomp protection

A large number of system calls are exposed to every userland process with many of them going unused for the entire lifetime of the process. As system calls change and mature, bugs are found and eradicated. A certain subset of userland applications benefit by having a reduced set of available system calls. The resulting set reduces the total kernel surface exposed to the application. System call filtering is meant for use with those applications.

Seccomp (short for *secure compute*) is a system call filtering mechanism present in the kernel. Initially it has been thought to be a sandboxing mechanism that would allow userspace processes to issue a very limited set of system calls - read(), write(), exit() and sigreturn(). This has been further known to be **seccomp mode 1**, and while it is strong on the security side, it doesn't leave much room for flexibility.

The next addition to seccomp was to allow filtering (or **seccomp mode 2**) based on the kernel BPF (Berkeley Packet Filter) infrastructure. This allows the system administrator to define complex and granular policies, per system call and its arguments. This is an extension to the BPF mechanism, that allows filtering to apply to system call numbers and their arguments, besides its original purpose (socket packets). The defined filter results in a seccomp policy which is attached to the userspace process in the form of a BPF program. Each time the process issues a system call, it is checked against this policy in order to determine how it will be handled:

- **SECCOMP_RET_KILL** - the task exits immediately without executing the system call.
- **SECCOMP_RET_TRAP** - the kernel sends a SIGSYS to the triggering task without executing the system call.
- **SECCOMP_RET_ERRNO** - a custom errno is returned to userspace without executing the system call.
- **SECCOMP_RET_TRACE** - causes the kernel to attempt to notify a ptrace-based tracer prior to executing the system call. The tracer can skip the system call or change it to a valid syscall number.
- **SECCOMP_RET_ALLOW** - results in the system call being executed.

In order to make the secure computing facility more userspace-friendly, the libseccomp library has been developed, which is meant to make it easier for applications to take advantage of the packet-filter-based seccomp mode. Prior to this, userspace applications had to define the BPF filter themselves. libseccomp restructures this approach into a simple and straightforward

API which userspace applications can use. The latest version of libseccomp adds support for Python bindings as well, and is designed to work on multiple architectures (ARM, MIPS). PowerPC support has also been merged on a separate branch, and is expected to be included in future releases.

Using seccomp with LXC containers

Please refer to Building LXC for information on how to build LXC with seccomp support in the SDK.

Note: Currently LXC seccomp support is not available for ARM64 architectures.

Seccomp filtering integrates well with processes sandboxed as containers, as they can be assigned to untrusted users and exposed with a limited set of allowed system calls. This is a portable and granular low-level security mechanism which can be used to increase container security. The seccomp policy file needs to be applied only to the init process in the container, and will be inherited by all its children.

The seccomp policy for the container is specified using the container configuration file, in the form of a single line containing:

```
lxc.seccomp = /var/lib/lxc/lxc_seccomp.conf
```

An example lxc_seccomp policy file can look as follows:

```
2
blacklist
[ppc64]
mknod errno 120
sched_setscheduler trap
fchmodat kill
[ppc]
mknod
```

The elements in the policy file represent the following:

1. Version number (1/2) - a single integer containing a single number, 1 or 2. Version 1 only allows to define a set of system calls which are allowed (whitelisted) in the container, specified by syscall number. This version is limited in configurability and portability, since it's only used to specify allowed syscall numbers, which may differ from arch to arch. Version 2 allows the policies to be either a whitelist (default deny, except mentioned syscalls) or a blacklist (default allow, except mentioned syscalls), and the syscalls can be expressed by name.
2. Policy type (whitelist/blacklist) - with an option of a default policy action (errno #, trap, kill, allow). The policy type is per seccomp context, and can be either whitelist or blacklist, not both.
3. Architecture tag [optional] - mentions that the following set of system calls will only be applied to a specific architecture. There can be multiple architecture tags and associated syscalls. These tags allow the same seccomp policy file to be used on multiple platforms, treating each one differently with respect to the set of system calls.
4. System calls - which can be expressed by number (in version 1) or name (in version 2). Optionally, an action can be expressed after the system call (errno #, trap, kill, allow), specifying the desired seccomp behavior. If this is omitted, the dafault rule action of the policy will be applied (allow for whitelist policies, kill for blacklist policies).

When running a container with the previous policy file on a PowerPC 64-bit platform, the mknod, sched_setscheduler (chrt) and fchmodat (chmod) system calls will be denied, with mentioned behaviors: mknod will return errno 120 without executing, chrt will trap and chmod will result in the process executing it being killed. On PowerPC platforms, only mknod will be denied, resulting in the process being killed. All other system calls will be allowed.

Notes:

- Containers can still be started without loading a seccomp policy file, simply by omitting the lxc.seccomp line in the config file. No seccomp policy is loaded by default.

- If a container process has a seccomp policy loaded, this can be seen in /proc/PID/status, on the seccomp line. This line will contain "Seccomp: 2" when using seccomp filter (mode 2). "Seccomp: 0" means there is no seccomp policy in effect.
- Seccomp policies of a process are automatically inherited by its children.
- Currently LXC supports only system call based filtering, with no support for system call arguments.
- The performance degradation of the processes running with a seccomp policy applied is directly proportional with the policy file size: normally, the system calls are listed as rules in the BPF filter program, and they all need to be parsed and matched at each system call. The longer the list, the more time this will take.
- The LXC package comes shipped with a set of example policy files which can be found at /share/doc/lxc/examples/seccomp-*. There's also a policy file, common.seccomp, which denies common security syscall threats in the container, such as kernel module manipulation, kexec and open_by_handle_at (the vector for the Shocker exploit).

11.4.5 Libvirt How To's

11.4.5.1 Basic Example

The following example shows the lifecycle of a simple LXC libvirt domain called *container1*. The virsh tool is used for managing the lxc domain lifecycle.

1. Confirm the host Linux configuration. Begin by confirming that the host kernel is configured correctly and that rootfs setup such as mounting cgroups has been done. This can be done with the lxc-checkconfig command.

```
# lxc-checkconfig
--- Namespaces ---
Namespaces: enabled
Utsname namespace: enabled
Ipc namespace: enabled
Pid namespace: enabled
User namespace: missing
Network namespace: enabled
Multiple /dev/pts instances: enabled

--- Control groups ---
Cgroup: enabled
Cgroup clone_children flag: enabled
Cgroup device: enabled
Cgroup sched: enabled
Cgroup cpu account: enabled
Cgroup memory controller: enabled
Cgroup cpuset: enabled

--- Misc ---
Veth pair device: enabled
Macvlan: enabled
Vlan: enabled
File capabilities: enabled
```

2. **Create a libvirt XML file defining the container**. The example below shows a very simple container defined in container1.xml that runs the command /bin/sh and has a console:

```
# cat container1.xml
<domain type='lxc'>
  <name>container1</name>
  <memory>500000</memory>
  <os>
    <type>exe</type>
```

```
    <init>/bin/sh</init>
  </os>
  <devices>
    <console type='pty'/>
  </devices>
</domain>
```

3. **Define the container.** The *virsh define* command processes the XML and makes creates the new libvirt domain.

```
# virsh -c lxc:/// define container1.xml
Domain container1 defined from container1.xml

# virsh -c lxc:/// list --all
 Id    Name                           State
----------------------------------------------------
 -     container1                     shut off
```

4. Start the container.

```
# virsh -c lxc:/// start container1
Domain container1 started

# virsh -c lxc:/// list
 Id    Name                           State
----------------------------------------------------
 3196  container1                     running
```

5. Connect to the console.

```
# virsh -c lxc:/// console container1
Connected to domain container1
Escape character is ^]
sh-4.2#
sh-4.2# ps -ef
UID        PID  PPID  C STIME TTY          TIME CMD
root         1     0  0 18:25 pts/2    00:00:00 /bin/sh
root         3     1  0 18:36 pts/2    00:00:00 ps -ef

sh-4.2# ifconfig br0
br0: flags=4163<UP,BROADCAST,RUNNING,MULTICAST>  mtu 1500
        inet 10.171.73.123  netmask 255.255.254.0  broadcast 10.171.73.255
        inet6 fe80::a00:27ff:fe01:fe07  prefixlen 64  scopeid 0x20<link>
        ether 08:00:27:01:fe:07  txqueuelen 0  (Ethernet)
        RX packets 865838  bytes 104029354 (99.2 MiB)
        RX errors 0  dropped 0  overruns 0  frame 0
        TX packets 104446  bytes 43998714 (41.9 MiB)
        TX errors 0  dropped 0 overruns 0  carrier 0  collisions 0

sh-4.2#
```

Press CTRL +] to exit the console.

The following aspects must be noted:

- the processes inside the container are running in a separate namespace, hence the different process hierarchy
- since no network configuration for the domain is explicitly specified, all networking interfaces are shared with the host (all the other interfaces are present too - br0 is mentioned as an example)

- since no filesystem configuration is specified for the domain, the filesystem is shared with the host-- all host mounts are present in the container as well.

6. To stop the container use the destroy command:

```
# virsh -c lxc:/// destroy container1
Domain container1 destroyed

# virsh -c lxc:/// list  --all
 Id    Name                           State
----------------------------------------------------
 -     container1                     shut off
```

7. To remove the domain from libvirt, use the undefine command.

```
# virsh -c lxc:/// undefine container1
Domain container1 has been undefined
```

11.4.6 USDPAA in LXC

This section describes running the USDPAA driver software in LXC containers. It presents the configuration steps for this scenario, along with observed issues and raised questions. Running USDPAA in containers is intended to be a proof of concept and a supported feature for the QorIQ SDK starting from v1.4. USDPAA is only available for DPAA v1.x platforms.

The P4080DS RefMan was also used to determine the proper SerDes Lane Configuration for the test board.

11.4.6.1 General Setup

Prerequisites

The test environment consisted of the following components in the **FSR Boardfarm**:

- a P4080DS board - **dumbo**
- a Linux test machine - **zro04qoriq02** with 2 test ports

The **dumbo** test board presents the following port configuration:

```
[b43198@zro04qoriqsrv ~]$ lars info dumbo
Name          : dumbo
Template      : P4080DS
Category      : board
Status        : reserved
Current user  : Purcareata Bogdan-B43198
Usable        : True

Station    : <Station(176)>
Console    : telnet://10.171.77.74:51201
Power      : adam5000://10.171.77.131/18

JTAG       : 10161212

Installed devices:
dumbo.duart_p1  : PORT
dumbo.rgmii_p1  : SERVICE
dumbo.sgmii_s3p1: MCCPORT
dumbo.sgmii_s3p2: MCCPORT
dumbo.sgmii_s3p3: SWITCH
```

```
dumbo.usb20_p1   : PORT
dumbo.xaui_s4p1 : PORT
```

The board exposes 2 SGMII ports available for testing, managed by Fman: *dumbo.sgmii_s3p1* and *dumbo.sgmii_s3p2*. These ports have been connected to the test machine as follows:

```
[b43198@zro04qoriqsrv][~]$ lars list links
zro04qoriq02.p1      <--->     dumbo.sgmii_s3p1
zro04qoriq02.p2      <--->     dumbo.sgmii_s3p2
```

The following software components have been compiled from the SDK:

- fman microcode - fsl_fman_ucode.bin
- rcw - R_PPSXN_0x10/rcw_13g_1500mhz_rev2.bin
- u-boot
- kernel - uImage--3.8-r15.1-p4080ds-20130527105557.bin
- device tree blob - uImage_sdk_1.4_23.05_usdpaa_multiple_1pool.dtb
- rootfs - fsl-image-core-p4080ds-20130527121546.rootfs.ext2.gz.u-boot

The device tree has been slightly modified in order to support multiple running instances of the USDPAA application. This modification will be detailed in subsection Running multiple USDPAA instances on page 2466.

Booting the Board

```
setenv kernelimage; setenv dtbimage; setenv rootfsimage;setenv bootargs console=ttyS0,115200;setenv
tftpram 'tftp 1000000 $kernelimage;tftp c00000 $dtbimage;tftp 2000000 $rootfsimage'; setenv bootram
'bootm 1000000 2000000 c00000'

setenv kernelimage b43198/uImage--3.8-r15.1-p4080ds-20130527105557.bin; setenv dtbimage b43198/
uImage_sdk_1.4_23.05_usdpaa_multiple_1pool.dtb; setenv rootfsimage b43198/fsl-image-core-
p4080ds-20130527121546.rootfs.ext2.gz.u-boot

setenv bootargs root=/dev/ram rw console=ttyS0,115200 usdpaa_mem=256M bportals=s0-1 qportals=s0-1

run tftpram; run bootram
```

Running a Single Reflector Process

According to the documentation, it takes 2 steps:

- running the Frame Manager Configuration tool (**fmc**) - NOTE: documentation states that this tool can be used only once
- running the reflector process

Both applications require 2 files:

- FMC Policy Definition File - PCD
- FMC Configuration Source File

These files are passed as arguments and must be the same for the two applications. The policy definition file can be the same regardless of SerDes configuration. The configuration source file is SerDes config dependent. Since the **dumbo** board exposes 2 SGMII ports, it has been booted with SerDes config 0x10 and the config file **usdpaa_config_p4_serdes_0x10.xml** has been modified as follows:

```
<cfgdata>
 <config>
  <engine name="fm1">
   <port type="1G" number="0" policy="hash_ipsec_src_dst_spi_policy6"/>
   <port type="1G" number="1" policy="hash_ipsec_src_dst_spi_policy7"/>
```

```
  </engine>
 </config>
</cfgdata>
```

This translates into calling **fmc** and **reflector** for interfaces **fm2-gb0** and **fm2-gb1**.

```
root@p4080ds:~# fmc -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -a
root@p4080ds:~# reflector -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -b

Testing

Testing has been done using the steps indicated in he documentation. The **zro04qoriq04** test workstation has been configured as follows:

- IP addresses:

```
ifconfig eth3 192.168.10.2 up
ifconfig eth4 192.168.20.2 up
```

- ARP entries:

```
arp -s 192.168.10.1 00:E0:0C:00:93:05
arp -s 192.168.20.1 00:E0:0C:00:93:06
```

Test commands:

```
[b43198@zro04qoriq04 ~]$ ping -c 3 192.168.10.1
PING 192.168.10.1 (192.168.10.1) 56(84) bytes of data.

```

11.4.6.2 Running multiple USDPAA instances

According to reference "Running multiple distinct PPAM application processes (or "instances" as they are sometimes described) requires that each process have its own dedicated set of FMAN interfaces, buffer pools, and cores".

The following resources need to be partitioned:

- interfaces - by using an additional **-i** parameter to the reflector application. Since Since there are only 2 FMan interfaces available on the board - **fm2-gb0** and **fm2-gb1** - the maximum number of USDPAA instances that can be run is 2.
- cores - by using an additional **cpu-range** parameter to the reflector application, in the form of '**index**' or '**first .. last**'. The reflector will start threads affine to the mentioned cores.
- buffer pools - this is more delicate and will be discussed in detail in the next subsection.

Partitioning Buffer Pools

Buffer pools are associated to Ethernet interfaces and the mappings are done in the device tree blob.

There should be distinct buffer pools for distinct USDPAA processes. When sharing buffer pools among different running processes, they fail with SEGFAULT.

Documentation states that "*Each PPAC-based application process will initialize the (usually 3) buffer pools used by each FMan interface that belongs to it. (If a buffer pool is used by more than one interface, it will only be initialised once.) By default the number of buffers to allocate for the triplet of pools used by an FMan interface is 0 for the first two pools and 1728 for the third. The default allocation triplet can be overridden via the -b option.*"

One can define 1, 2 or 3 buffer pools per FMan interface. When doing custom seeding via the -b parameter - which only accepts a triplet x:y:z - the first value (x) corresponds to the first bufer, the second (y) corresponds to the second buffer and the third value (z) to the third buffer. If an interface only has 1 associated buffer pool, passing *-b 120:0:0* is valid, as it will seed only the 1st buffer pool - the interface's only one; if it has 2 buffer pools - *-b 120:120:0* is also valid. You may also pass other values than 0 in the triplets - since they don't have any buffer pool correspondence, they will be discarded. One must seed the buffer pool with respect to the DMA memory size allocated for USDPAA and passed via the **usdpaa_mem** boot argument.

The following is a snippet from the device tree containing the buffer pools for interfaces **fm2-gb0** (*ethernet@5*) and **fm2-gb1** (*ethernet@6*).

```
[ ... ]

2167     ethernet@5 {
2168       compatible = "fsl,p4080-dpa-ethernet-init", "fsl,dpa-ethernet-init";
2169       fsl,fman-mac = <0x59>;
2170       fsl,bman-buffer-pools = <0x53>;
2171       fsl,qman-frame-queues-rx = <0x5c 0x1 0x5d 0x1>;
2172       fsl,qman-frame-queues-tx = <0x7c 0x1 0x7d 0x1>;
2173     };
2174
2175     ethernet@6 {
2176       compatible = "fsl,p4080-dpa-ethernet-init", "fsl,dpa-ethernet-init";
2177       fsl,fman-mac = <0x5a>;
2178       fsl,bman-buffer-pools = <0x54>;
2179       fsl,qman-frame-queues-rx = <0x5e 0x1 0x5f 0x1>;
2180       fsl,qman-frame-queues-tx = <0x7e 0x1 0x7f 0x1>;
2181     };
```

```
[ ... ]

2214   buffer-pool@7 {
2215     compatible = "fsl,p4080-bpool", "fsl,bpool";
2216     fsl,bpid = <0x7>;
2217     fsl,bpool-ethernet-cfg = <0x0 0x0 0x0 0xc0 0x0 0xdeadbeef>;
2218     fsl,bpool-thresholds = <0x400 0xc00 0x0 0x0>;
2219     linux,phandle = <0x52>;
2220     phandle = <0x52>;
2221   };
2222
2223   buffer-pool@8 {
2224     compatible = "fsl,p4080-bpool", "fsl,bpool";
2225     fsl,bpid = <0x8>;
2226     fsl,bpool-ethernet-cfg = <0x0 0x0 0x0 0x240 0x0 0xabbaf00d>;
2227     fsl,bpool-thresholds = <0x100 0x300 0x0 0x0>;
2228     linux,phandle = <0x53>;
2229     phandle = <0x53>;
2230   };
2231
2232   buffer-pool@9 {
2233     compatible = "fsl,p4080-bpool", "fsl,bpool";
2234     fsl,bpid = <0x9>;
2235     fsl,bpool-ethernet-cfg = <0x0 0x0 0x0 0x6c0 0x0 0xfeedabba>;
2236     fsl,bpool-thresholds = <0x100 0x300 0x0 0x0>;
2237     linux,phandle = <0x54>;
2238     phandle = <0x54>;
2239   };

[ ... ]
```

Running 2 Reflectors

To run 2 instances of the reflector application, one must:

- run the fmc tool - only once
- run 2 reflector processes

The fmc tool is passed an .xml config file containing both FMan interfaces present on the board. In order to provide each reflector instance with a different interface, you can either:

- pass a .xml config file describing only that particular interface;
- pass a .xml config file with both interfaces, but also pass an additional **-i** parameter, specifying the designated one.

The differential config files may look as follows:

- **usdpaa_config_p4_serdes_0x10_0.xml** - only fm2-gb0 is present:

```
<cfgdata>
 <config>
  <engine name="fm1">
   <port type="1G" number="0" policy="hash_ipsec_src_dst_spi_policy6"/>
  </engine>
 </config>
</cfgdata>
```

- **usdpaa_config_p4_serdes_0x10_1.xml** - only fm2-gb1 is present:

```
<cfgdata>
 <config>
  <engine name="fm1">
```

```
    <port type="1G" number="1" policy="hash_ipsec_src_dst_spi_policy7"/>
   </engine>
  </config>
 </cfgdata>
```

In order to run 2 reflectors, you can issue the following commands - one in each terminal:

```
reflector -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -b 120:0:0 -i fm2-gb0
0..1
reflector -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -b 120:0:0 -i fm2-gb1
4..5
```

... or these:

```
reflector -c usdpaa_config_p4_serdes_0x10_0.xml -p usdpaa_policy_hash_ipv4.xml -b 120:0:0 0..1
reflector -c usdpaa_config_p4_serdes_0x10_1.xml -p usdpaa_policy_hash_ipv4.xml -b 120:0:0 4..5
```

11.4.6.3 Running Reflector in Containers

Inspecting the Reflector App

The first step in investigating reflector behavior was to **strace** it. Since strace exposes application syscalls, and containers are running with the same kernel as the host, this should be an appropriate approach.

Looking at the results, the reflector opens the following files:

- /lib/* - library files;
- /proc/device-tree/* - the entire board device tree (.dtb);
- the passed .xml config files;
- /dev/mem - access portal memory mappings;
- /dev/fsl-usdpaa - manage the kernel DPAA resource allocator;
- /dev/fsl-usdpaa-irq - interrupt controller device (replacement for /dev/uio* entries);
- /etc/terminfo/* - terminal settings.

In order to run the test, all these files must be present in the container filesystem. Each container filesystem is configured to contain the /dev/mem and /dev/fsl-usdpaa devices - these are shared. Since SDK 1.4, the /dev/bman-uio and /dev/qman-uio entries have been replaced with a common **/dev/fsl-usdpaa-irq** device used by the processes to register to receiving the interrupts. This device is shared among the containers as well. These devices will then be created with mknod commands inside each container.

Running the test

NOTE: commands are shown for one container only; commands for the other container are issued symmetrically.

1. mount the croups filesystem on host - requirement of LXC (see Host Root Filesystem Configuration for Linux Containers on page 2436).
2. run the fmc tool on host - the fmc tool is used to initialize the FMan kernel driver and should be run only once after each successful boot, regardless of how many USDPAA application instances are started/stopped afterwards. It has no particular importance whether this is run on the host or inside a container, since its purpose is to configure kernel space variables - and these are shared between the host and the containers. Considering this aspect, and the fact that fmc should be run only once, it is best for it to be run on the host, before starting any USDPAA aplication:

   ```
   # fmc -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -a
   ```

3. edit the LXC container config file - **lxc-usdpaa-1.conf** - doing the following:
   - set container name

- enable device rights
- set dedicated cores

```
lxc.utsname = usdpaa1

# You may add some other parameters here if you like

# First deny all device access , then allow specific ones
lxc.cgroup.devices.deny = a

# Enable console and terminal devices
lxc.cgroup.devices.allow = c 5:* rwm # console
lxc.cgroup.devices.allow = c 4:* rwm # tty0
lxc.cgroup.devices.allow = c 136:* rwm # tty1
# Enable other devices access
lxc.cgroup.devices.allow = b 1:0 rwm # ram0
lxc.cgroup.devices.allow = c 1:3 rwm # null
lxc.cgroup.devices.allow = c 1:9 rwm # urandom
# Enable usdpaa
lxc.cgroup.devices.allow = c 10:61 rwm # fsl-usdpaa-irq
lxc.cgroup.devices.allow = c 10:62 rwm # fsl-usdpaa
lxc.cgroup.devices.allow = c 1:1 rwm # mem

# Dedicated cores
lxc.cgroup.cpuset.cpus = 0,1,2,3
```

4. create and start the container:

```
root@p4080ds:~# lxc-create -n foo1 -t busybox -f lxc-usdpaa-1.conf
setting root password to "root"
Password for 'root' changed
'busybox' template installed
'foo1' created
root@p4080ds:~# lxc-start -n foo1 -d
root@p4080ds:~# lxc-console -n foo1

Type <Ctrl+a q> to exit the console, <Ctrl+a Ctrl+a> to enter Ctrl+a itself

foo1 login: root
Password: root
~ #
```

5. copy binaries and xml files from host:

```
# reflector binary
root@p4080ds:~# mkdir -p /var/lib/lxc/foo1/rootfs/usr/bin
root@p4080ds:~# cp /usr/bin/reflector /var/lib/lxc/foo1/rootfs/usr/bin/
# usdpaa local xmls
root@p4080ds:~# cp usdpaa_* /var/lib/lxc/foo1/rootfs/root/
# terminfo settings
root@p4080ds:~# mkdir -p /var/lib/lxc/foo1/rootfs/etc/terminfo
root@p4080ds:~# cp -R /etc/terminfo/* /var/lib/lxc/foo1/rootfs/etc/terminfo/
```

6. setup the container - create devices in /dev:

```
~ # mknod /dev/fsl-usdpaa-irq c 10 61
~ # mknod /dev/fsl-usdpaa c 10 62
~ # mknod /dev/mem c 1 1
```

7. run reflector in container:

```
~ # reflector -c usdpaa_config_p4_serdes_0x10.xml -p usdpaa_policy_hash_ipv4.xml -b 120:0:0 -i
fm2-gb0 0..3
Found /fsl,dpaa/dpa-fman0-oh@1, Tx Channel = 46, FMAN = 0, Port ID = 1
Found /fsl,dpaa/ethernet@5, Tx Channel = 61, FMAN = 1, Port ID = 0
Found /fsl,dpaa/ethernet@6, Tx Channel = 62, FMAN = 1, Port ID = 1
Found /fsl,dpaa/ethernet@9, Tx Channel = 60, FMAN = 1, Port ID = 0
WARN:Can't find Qman clock frequency
Configuring for 1 network interface
Allocated DMA region size 0x1000000
reflector starting
Released 120 bufs to BPID 8
Thread uid:0 alive (on cpu 0)
Thread uid:1 alive (on cpu 1)
Thread uid:2 alive (on cpu 2)
Thread uid:3 alive (on cpu 3)
reflector>
```

8. test from Linux PC:

```
[b43198@zro04qoriq04 ~]$ ping -c 3 192.168.10.1
PING 192.168.10.1 (192.168.10.1) 56(84) bytes of data.
64 bytes from 192.168.10.1: icmp_seq=1 ttl=64 time=0.177 ms
64 bytes from 192.168.10.1: icmp_seq=2 ttl=64 time=0.217 ms
64 bytes from 192.168.10.1: icmp_seq=3 ttl=64 time=0.321 ms

--- 192.168.10.1 ping statistics ---
3 packets transmitted, 3 received, 0% packet loss, time 2037ms
rtt min/avg/max/mdev = 0.177/0.238/0.321/0.061 ms
```

By following the same steps for the second container - with slight modications regarding the container name and assigned resources - another reflector instance can be successfully started and run in parallel with the first one, for the second FMan interface **fm2-gb1**.

11.4.7 Appendix

11.4.7.1 LXC Configuration File Reference

The text below comes from the lxc.conf.5 man page:

```
LXC.CONF(5)                                                        LXC.CONF(5)
NAME

       lxc.conf - Configuration files for LXC.
DESCRIPTION

       LXC configuration is split in two parts. Container configuration and
       system configuration.

   CONTAINER CONFIGURATION
       The container configuration is held in the config stored in the
       container's directory.

       A basic configuration is generated at container creation time with
       the default's recommended for the chosen template as well as extra
       default keys coming from the default.conf file.
```

```
       That default.conf file is either located at
       /usr/local/etc/lxc/default.conf or for unprivileged containers at
       ~/.config/lxc/default.conf.

       Details about the syntax of this file can be found in:
       lxc.container.conf(5)

   SYSTEM CONFIGURATION
       The system configuration is located at /usr/local/etc/lxc/lxc.conf or
       ~/.config/lxc/lxc.conf for unprivileged containers.

       This configuration file is used to set values such as default lookup
       paths and storage backend settings for LXC.

       Details about the syntax of this file can be found in:
       lxc.system.conf(5)

The text below comes from the lxc.container.conf.5 man page:

```
LXC.CONTAINER.CONF(5)                                  LXC.CONTAINER.CONF(5)
NAME

       lxc.container.conf - LXC container configuration file

DESCRIPTION

       The linux containers (lxc) are always created before being used. This
       creation defines a set of system resources to be virtualized /
       isolated when a process is using the container. By default, the pids,
       sysv ipc and mount points are virtualized and isolated. The other
       system resources are shared across containers, until they are
       explicitly defined in the configuration file. For example, if there
       is no network configuration, the network will be shared between the
       creator of the container and the container itself, but if the network
       is specified, a new network stack is created for the container and
       the container can no longer use the network of its ancestor.

       The configuration file defines the different system resources to be
       assigned for the container. At present, the utsname, the network, the
       mount points, the root file system, the user namespace, and the
```

```
       control groups are supported.

       Each option in the configuration file has the form key = value
       fitting in one line. The '#' character means the line is a comment.

   CONFIGURATION
       In order to ease administration of multiple related containers, it is
       possible to have a container configuration file cause another file to
       be loaded. For instance, network configuration can be defined in one
       common file which is included by multiple containers. Then, if the
       containers are moved to another host, only one file may need to be
       updated.

       lxc.include
              Specify the file to be included. The included file must be in
              the same valid lxc configuration file format.

   ARCHITECTURE
       Allows one to set the architecture for the container. For example,
       set a 32bits architecture for a container running 32bits binaries on
       a 64bits host. This fixes the container scripts which rely on the
       architecture to do some work like downloading the packages.

       lxc.arch
              Specify the architecture for the container.

              Valid options are x86, i686, x86_64, amd64

   HOSTNAME
       The utsname section defines the hostname to be set for the container.
       That means the container can set its own hostname without changing
       the one from the system. That makes the hostname private for the
       container.

       lxc.utsname
              specify the hostname for the container

   HALT SIGNAL
       Allows one to specify signal name or number, sent by lxc-stop to the
       container's init process to cleanly shutdown the container. Different
       init systems could use different signals to perform clean shutdown
       sequence. This option allows the signal to be specified in kill(1)
       fashion, e.g. SIGPWR, SIGRTMIN+14, SIGRTMAX-10 or plain number. The
       default signal is SIGPWR.

       lxc.haltsignal
              specify the signal used to halt the container

   STOP SIGNAL
       Allows one to specify signal name or number, sent by lxc-stop to
       forcibly shutdown the container. This option allows signal to be
       specified in kill(1) fashion, e.g. SIGKILL, SIGRTMIN+14, SIGRTMAX-10
       or plain number.  The default signal is SIGKILL.

       lxc.stopsignal
              specify the signal used to stop the container

   NETWORK
       The network section defines how the network is virtualized in the
       container. The network virtualization acts at layer two. In order to
```

```
       use the network virtualization, parameters must be specified to
       define the network interfaces of the container. Several virtual
       interfaces can be assigned and used in a container even if the system
       has only one physical network interface.

       lxc.network.type
              specify what kind of network virtualization to be used for the
              container. Each time a lxc.network.type field is found a new
              round of network configuration begins. In this way, several
              network virtualization types can be specified for the same
              container, as well as assigning several network interfaces for
              one container. The different virtualization types can be:

              none: will cause the container to share the host's network
              namespace. This means the host network devices are usable in
              the container. It also means that if both the container and
              host have upstart as init, 'halt' in a container (for
              instance) will shut down the host.

              empty: will create only the loopback interface.

              veth: a peer network device is created with one side assigned
              to the container and the other side is attached to a bridge
              specified by the lxc.network.link. If the bridge is not
              specified, then the veth pair device will be created but not
              attached to any bridge. Otherwise, the bridge has to be setup
              before on the system, lxc won't handle any configuration
              outside of the container. By default lxc choose a name for the
              network device belonging to the outside of the container, this
              name is handled by lxc, but if you wish to handle this name
              yourself, you can tell lxc to set a specific name with the
              lxc.network.veth.pair option.

              vlan: a vlan interface is linked with the interface specified
              by the lxc.network.link and assigned to the container. The
              vlan identifier is specified with the option
              lxc.network.vlan.id.

              macvlan: a macvlan interface is linked with the interface
              specified by the lxc.network.link and assigned to the
              container.  lxc.network.macvlan.mode specifies the mode the
              macvlan will use to communicate between different macvlan on
              the same upper device. The accepted modes are private, the
              device never communicates with any other device on the same
              upper_dev (default), vepa, the new Virtual Ethernet Port
              Aggregator (VEPA) mode, it assumes that the adjacent bridge
              returns all frames where both source and destination are local
              to the macvlan port, i.e. the bridge is set up as a reflective
              relay. Broadcast frames coming in from the upper_dev get
              flooded to all macvlan interfaces in VEPA mode, local frames
              are not delivered locally, or bridge, it provides the behavior
              of a simple bridge between different macvlan interfaces on the
              same port. Frames from one interface to another one get
              delivered directly and are not sent out externally. Broadcast
              frames get flooded to all other bridge ports and to the
              external interface, but when they come back from a reflective
              relay, we don't deliver them again. Since we know all the MAC
              addresses, the macvlan bridge mode does not require learning
              or STP like the bridge module does.
```

```
              phys: an already existing interface specified by the
              lxc.network.link is assigned to the container.

       lxc.network.flags
              specify an action to do for the network.

              up: activates the interface.

       lxc.network.link
              specify the interface to be used for real network traffic.

       lxc.network.mtu
              specify the maximum transfer unit for this interface.

       lxc.network.name
              the interface name is dynamically allocated, but if another
              name is needed because the configuration files being used by
              the container use a generic name, eg. eth0, this option will
              rename the interface in the container.

       lxc.network.hwaddr
              the interface mac address is dynamically allocated by default
              to the virtual interface, but in some cases, this is needed to
              resolve a mac address conflict or to always have the same
              link-local ipv6 address.  Any "x" in address will be replaced
              by random value, this allows setting hwaddr templates.

       lxc.network.ipv4
              specify the ipv4 address to assign to the virtualized
              interface. Several lines specify several ipv4 addresses.  The
              address is in format x.y.z.t/m, eg. 192.168.1.123/24. The
              broadcast address should be specified on the same line, right
              after the ipv4 address.

       lxc.network.ipv4.gateway
              specify the ipv4 address to use as the gateway inside the
              container. The address is in format x.y.z.t, eg.
              192.168.1.123.  Can also have the special value auto, which
              means to take the primary address from the bridge interface
              (as specified by the lxc.network.link option) and use that as
              the gateway. auto is only available when using the veth and
              macvlan network types.

       lxc.network.ipv6
              specify the ipv6 address to assign to the virtualized
              interface. Several lines specify several ipv6 addresses.  The
              address is in format x::y/m, eg.
              2003:db8:1:0:214:1234:fe0b:3596/64

       lxc.network.ipv6.gateway
              specify the ipv6 address to use as the gateway inside the
              container. The address is in format x::y, eg. 2003:db8:1:0::1
              Can also have the special value auto, which means to take the
              primary address from the bridge interface (as specified by the
              lxc.network.link option) and use that as the gateway. auto is
              only available when using the veth and macvlan network types.

       lxc.network.script.up
              add a configuration option to specify a script to be executed
              after creating and configuring the network used from the host
```

```
              side. The following arguments are passed to the script:
              container name and config section name (net) Additional
              arguments depend on the config section employing a script
              hook; the following are used by the network system: execution
              context (up), network type (empty/veth/macvlan/phys),
              Depending on the network type, other arguments may be passed:
              veth/macvlan/phys. And finally (host-sided) device name.

              Standard output from the script is logged at debug level.
              Standard error is not logged, but can be captured by the hook
              redirecting its standard error to standard output.

      lxc.network.script.down
              add a configuration option to specify a script to be executed
              before destroying the network used from the host side. The
              following arguments are passed to the script: container name
              and config section name (net) Additional arguments depend on
              the config section employing a script hook; the following are
              used by the network system: execution context (down), network
              type (empty/veth/macvlan/phys), Depending on the network type,
              other arguments may be passed: veth/macvlan/phys. And finally
              (host-sided) device name.

              Standard output from the script is logged at debug level.
              Standard error is not logged, but can be captured by the hook
              redirecting its standard error to standard output.

  NEW PSEUDO TTY INSTANCE (DEVPTS)
      For stricter isolation the container can have its own private
      instance of the pseudo tty.

      lxc.pts
              If set, the container will have a new pseudo tty instance,
              making this private to it. The value specifies the maximum
              number of pseudo ttys allowed for a pts instance (this
              limitation is not implemented yet).

  CONTAINER SYSTEM CONSOLE
      If the container is configured with a root filesystem and the inittab
      file is setup to use the console, you may want to specify where the
      output of this console goes.

      lxc.console
              Specify a path to a file where the console output will be
              written. The keyword 'none' will simply disable the console.
              This is dangerous once if have a rootfs with a console device
              file where the application can write, the messages will fall
              in the host.

  CONSOLE THROUGH THE TTYS
      This option is useful if the container is configured with a root
      filesystem and the inittab file is setup to launch a getty on the
      ttys. The option specifies the number of ttys to be available for the
      container. The number of gettys in the inittab file of the container
      should not be greater than the number of ttys specified in this
      option, otherwise the excess getty sessions will die and respawn
      indefinitely giving annoying messages on the console or in
      /var/log/messages.

      lxc.tty
```

```
            Specify the number of tty to make available to the container.

CONSOLE DEVICES LOCATION
    LXC consoles are provided through Unix98 PTYs created on the host and
    bind-mounted over the expected devices in the container.  By default,
    they are bind-mounted over /dev/console and /dev/ttyN. This can
    prevent package upgrades in the guest. Therefore you can specify a
    directory location (under /dev under which LXC will create the files
    and bind-mount over them. These will then be symbolically linked to
    /dev/console and /dev/ttyN.  A package upgrade can then succeed as it
    is able to remove and replace the symbolic links.

    lxc.devttydir
           Specify a directory under /dev under which to create the
           container console devices.

/DEV DIRECTORY
    By default, lxc creates a few symbolic links (fd,stdin,stdout,stderr)
    in the container's /dev directory but does not automatically create
    device node entries. This allows the container's /dev to be set up as
    needed in the container rootfs. If lxc.autodev is set to 1, then
    after mounting the container's rootfs LXC will mount a fresh tmpfs
    under /dev (limited to 100k) and fill in a minimal set of initial
    devices.  This is generally required when starting a container
    containing a "systemd" based "init" but may be optional at other
    times. Additional devices in the containers /dev directory may be
    created through the use of the lxc.hook.autodev hook.

    lxc.autodev
           Set this to 1 to have LXC mount and populate a minimal /dev
           when starting the container.

ENABLE KMSG SYMLINK
    Enable creating /dev/kmsg as symlink to /dev/console. This defaults
    to 1.

    lxc.kmsg
           Set this to 0 to disable /dev/kmsg symlinking.

MOUNT POINTS
    The mount points section specifies the different places to be
    mounted. These mount points will be private to the container and
    won't be visible by the processes running outside of the container.
    This is useful to mount /etc, /var or /home for examples.

    lxc.mount
           specify a file location in the fstab format, containing the
           mount information. The mount target location can and in most
           cases should be a relative path, which will become relative to
           the mounted container root. For instance,

           proc proc proc nodev,noexec,nosuid 0 0

           Will mount a proc filesystem under the container's /proc,
           regardless of where the root filesystem comes from. This is
           resilient to block device backed filesystems as well as
           container cloning.

           Note that when mounting a filesystem from an image file or
           block device the third field (fs_vfstype) cannot be auto as
```

```
               with mount(8) but must be explicitly specified.

       lxc.mount.entry
               specify a mount point corresponding to a line in the fstab
               format.

       lxc.mount.auto
               specify which standard kernel file systems should be
               automatically mounted. This may dramatically simplify the
               configuration. The file systems are:

               · proc:mixed (or proc): mount /proc as read-write, but remount
                 /proc/sys and /proc/sysrq-trigger read-only for security /
                 container isolation purposes.

               · proc:rw: mount /proc as read-write

               · sys:ro (or sys): mount /sys as read-only for security /
                 container isolation purposes.

               · sys:rw: mount /sys as read-write

               · cgroup:mixed: mount a tmpfs to /sys/fs/cgroup, create
                 directories for all hierarchies to which the container is
                 added, create subdirectories there with the name of the
                 cgroup, and bind-mount the container's own cgroup into that
                 directory.  The container will be able to write to its own
                 cgroup directory, but not the parents, since they will be
                 remounted read-only

               · cgroup:ro: similar to cgroup:mixed, but everything will be
                 mounted read-only.

               · cgroup:rw: similar to cgroup:mixed, but everything will be
                 mounted read-write. Note that the paths leading up to the
                 container's own cgroup will be writable, but will not be a
                 cgroup filesystem but just part of the tmpfs of
                 /sys/fs/cgroup

               · cgroup (without specifier): defaults to cgroup:rw if the
                 container retains the CAP_SYS_ADMIN capability, cgroup:mixed
                 otherwise.

               · cgroup-full:mixed: mount a tmpfs to /sys/fs/cgroup, create
                 directories for all hierarchies to which the container is
                 added, bind-mount the hierarchies from the host to the
                 container and make everything read-only except the
                 container's own cgroup. Note that compared to cgroup, where
                 all paths leading up to the container's own cgroup are just
                 simple directories in the underlying tmpfs, here
                 /sys/fs/cgroup/$hierarchy will contain the host's full
                 cgroup hierarchy, albeit read-only outside the container's
                 own cgroup.  This may leak quite a bit of information into
                 the container.

               · cgroup-full:ro: similar to cgroup-full:mixed, but everything
                 will be mounted read-only.

               · cgroup-full:rw: similar to cgroup-full:mixed, but everything
                 will be mounted read-write. Note that in this case, the
```

```
                container may escape its own cgroup. (Note also that if the
                container has CAP_SYS_ADMIN support and can mount the cgroup
                filesystem itself, it may do so anyway.)

              · cgroup-full (without specifier): defaults to cgroup-full:rw
                if the container retains the CAP_SYS_ADMIN capability,
                cgroup-full:mixed otherwise.

       Note that if automatic mounting of the cgroup filesystem is enabled,
       the tmpfs under /sys/fs/cgroup will always be mounted read-write (but
       for the :mixed and :ro cases, the individual hierarchies,
       /sys/fs/cgroup/$hierarchy, will be read-only). This is in order to
       work around a quirk in Ubuntu's mountall(8) command that will cause
       containers to wait for user input at boot if /sys/fs/cgroup is
       mounted read-only and the container can't remount it read-write due
       to a lack of CAP_SYS_ADMIN.

       Examples:

                  lxc.mount.auto = proc sys cgroup
                  lxc.mount.auto = proc:rw sys:rw cgroup-full:rw

   ROOT FILE SYSTEM
       The root file system of the container can be different than that of
       the host system.

       lxc.rootfs
              specify the root file system for the container. It can be an
              image file, a directory or a block device. If not specified,
              the container shares its root file system with the host.

              For directory or simple block-device backed containers, a
              pathname can be used. If the rootfs is backed by a nbd device,
              then nbd:file:1 specifies that file should be attached to a
              nbd device, and partition 1 should be mounted as the rootfs.
              nbd:file specifies that the nbd device itself should be
              mounted. overlayfs:/lower:/upper specifies that the rootfs
              should be an overlay with /upper being mounted read-write over
              a read-only mount of /lower.  aufs:/lower:/upper does the same
              using aufs in place of overlayfs. loop:/file tells lxc to
              attach /file to a loop device and mount the loop device.

       lxc.rootfs.mount
              where to recursively bind lxc.rootfs before pivoting. This is
              to ensure success of the pivot_root(8) syscall. Any directory
              suffices, the default should generally work.

       lxc.rootfs.options
              extra mount options to use when mounting the rootfs.

       lxc.pivotdir
              where to pivot the original root file system under lxc.rootfs,
              specified relatively to that. The default is mnt.  It is
              created if necessary, and also removed after unmounting
              everything from it during container setup.

   CONTROL GROUP
       The control group section contains the configuration for the
       different subsystem. lxc does not check the correctness of the
       subsystem name. This has the disadvantage of not detecting
```

```
       configuration errors until the container is started, but has the
       advantage of permitting any future subsystem.

       lxc.cgroup.[subsystem name]
              specify the control group value to be set. The subsystem name
              is the literal name of the control group subsystem. The
              permitted names and the syntax of their values is not dictated
              by LXC, instead it depends on the features of the Linux kernel
              running at the time the container is started, eg.
              lxc.cgroup.cpuset.cpus

   CAPABILITIES
       The capabilities can be dropped in the container if this one is run
       as root.

       lxc.cap.drop
              Specify the capability to be dropped in the container. A
              single line defining several capabilities with a space
              separation is allowed. The format is the lower case of the
              capability definition without the "CAP_" prefix, eg.
              CAP_SYS_MODULE should be specified as sys_module. See
              capabilities(7),

       lxc.cap.keep
              Specify the capability to be kept in the container. All other
              capabilities will be dropped.

   APPARMOR PROFILE
       If lxc was compiled and installed with apparmor support, and the host
       system has apparmor enabled, then the apparmor profile under which
       the container should be run can be specified in the container
       configuration. The default is lxc-container-default.

       lxc.aa_profile
              Specify the apparmor profile under which the container should
              be run. To specify that the container should be unconfined,
              use

              lxc.aa_profile = unconfined

   SELINUX CONTEXT
       If lxc was compiled and installed with SELinux support, and the host
       system has SELinux enabled, then the SELinux context under which the
       container should be run can be specified in the container
       configuration. The default is unconfined_t, which means that lxc will
       not attempt to change contexts.

       lxc.se_context
              Specify the SELinux context under which the container should
              be run or unconfined_t. For example

              lxc.se_context = unconfined_u:unconfined_r:lxc_t:s0-s0:c0.c1023

   SECCOMP CONFIGURATION
       A container can be started with a reduced set of available system
       calls by loading a seccomp profile at startup. The seccomp
       configuration file must begin with a version number on the first
       line, a policy type on the second line, followed by the
       configuration.
```

```
       Versions 1 and 2 are currently supported. In version 1, the policy is
       a simple whitelist. The second line therefore must read "whitelist",
       with the rest of the file containing one (numeric) sycall number per
       line. Each syscall number is whitelisted, while every unlisted number
       is blacklisted for use in the container

       In version 2, the policy may be blacklist or whitelist, supports per-
       rule and per-policy default actions, and supports per-architecture
       system call resolution from textual names.

       An example blacklist policy, in which all system calls are allowed
       except for mknod, which will simply do nothing and return 0
       (success), looks like:

       2
       blacklist
       mknod errno 0

       lxc.seccomp
              Specify a file containing the seccomp configuration to load
              before the container starts.

   UID MAPPINGS
       A container can be started in a private user namespace with user and
       group id mappings. For instance, you can map userid 0 in the
       container to userid 200000 on the host. The root user in the
       container will be privileged in the container, but unprivileged on
       the host. Normally a system container will want a range of ids, so
       you would map, for instance, user and group ids 0 through 20,000 in
       the container to the ids 200,000 through 220,000.

       lxc.id_map
              Four values must be provided. First a character, either 'u',
              or 'g', to specify whether user or group ids are being mapped.
              Next is the first userid as seen in the user namespace of the
              container. Next is the userid as seen on the host. Finally, a
              range indicating the number of consecutive ids to map.

   CONTAINER HOOKS
       Container hooks are programs or scripts which can be executed at
       various times in a container's lifetime.

       When a container hook is executed, information is passed both as
       command line arguments and through environment variables.  The
       arguments are:

       · Container name.

       · Section (always 'lxc').

       · The hook type (i.e. 'clone' or 'pre-mount').

       · Additional arguments In the case of the clone hook, any extra
         arguments passed to lxc-clone will appear as further arguments to
         the hook.

       The following environment variables are set:

       · LXC_NAME: is the container's name.
```

```
       · LXC_ROOTFS_MOUNT: the path to the mounted root filesystem.

       · LXC_CONFIG_FILE: the path to the container configuration file.

       · LXC_SRC_NAME: in the case of the clone hook, this is the original
         container's name.

       · LXC_ROOTFS_PATH: this is the lxc.rootfs entry for the container.
         Note this is likely not where the mounted rootfs is to be found,
         use LXC_ROOTFS_MOUNT for that.

      Standard output from the hooks is logged at debug level.  Standard
      error is not logged, but can be captured by the hook redirecting its
      standard error to standard output.

      lxc.hook.pre-start
             A hook to be run in the host's namespace before the container
             ttys, consoles, or mounts are up.

      lxc.hook.pre-mount
             A hook to be run in the container's fs namespace but before
             the rootfs has been set up. This allows for manipulation of
             the rootfs, i.e. to mount an encrypted filesystem. Mounts done
             in this hook will not be reflected on the host (apart from
             mounts propagation), so they will be automatically cleaned up
             when the container shuts down.

      lxc.hook.mount
             A hook to be run in the container's namespace after mounting
             has been done, but before the pivot_root.

      lxc.hook.autodev
             A hook to be run in the container's namespace after mounting
             has been done and after any mount hooks have run, but before
             the pivot_root, if lxc.autodev == 1.  The purpose of this hook
             is to assist in populating the /dev directory of the container
             when using the autodev option for systemd based containers.
             The container's /dev directory is relative to the
             ${LXC_ROOTFS_MOUNT} environment variable available when the
             hook is run.

      lxc.hook.start
             A hook to be run in the container's namespace immediately
             before executing the container's init. This requires the
             program to be available in the container.

      lxc.hook.post-stop
             A hook to be run in the host's namespace after the container
             has been shut down.

      lxc.hook.clone
             A hook to be run when the container is cloned to a new one.
             See lxc-clone(1) for more information.

  CONTAINER HOOKS ENVIRONMENT VARIABLES
      A number of environment variables are made available to the startup
      hooks to provide configuration information and assist in the
      functioning of the hooks. Not all variables are valid in all
      contexts. In particular, all paths are relative to the host system
      and, as such, not valid during the lxc.hook.start hook.
```

```
    LXC_NAME
           The LXC name of the container. Useful for logging messages in
           common log environments. [-n]

    LXC_CONFIG_FILE
           Host relative path to the container configuration file. This
           gives the container to reference the original, top level,
           configuration file for the container in order to locate any
           additional configuration information not otherwise made
           available. [-f]

    LXC_CONSOLE
           The path to the console output of the container if not NULL.
           [-c] [lxc.console]

    LXC_CONSOLE_LOGPATH
           The path to the console log output of the container if not
           NULL.  [-L]

    LXC_ROOTFS_MOUNT
           The mount location to which the container is initially bound.
           This will be the host relative path to the container rootfs
           for the container instance being started and is where changes
           should be made for that instance.  [lxc.rootfs.mount]

    LXC_ROOTFS_PATH
           The host relative path to the container root which has been
           mounted to the rootfs.mount location.  [lxc.rootfs]

LOGGING
    Logging can be configured on a per-container basis. By default,
    depending upon how the lxc package was compiled, container startup is
    logged only at the ERROR level, and logged to a file named after the
    container (with '.log' appended) either under the container path, or
    under /usr/local/var/log/lxc.

    Both the default log level and the log file can be specified in the
    container configuration file, overriding the default behavior. Note
    that the configuration file entries can in turn be overridden by the
    command line options to lxc-start.

    lxc.loglevel
           The level at which to log. The log level is an integer in the
           range of 0..8 inclusive, where a lower number means more
           verbose debugging. In particular 0 = trace, 1 = debug, 2 =
           info, 3 = notice, 4 = warn, 5 = error, 6 = critical, 7 =
           alert, and 8 = fatal. If unspecified, the level defaults to 5
           (error), so that only errors and above are logged.

           Note that when a script (such as either a hook script or a
           network interface up or down script) is called, the script's
           standard output is logged at level 1, debug.

    lxc.logfile
           The file to which logging info should be written.

AUTOSTART
    The autostart options support marking which containers should be
    auto-started and in what order. These options may be used by LXC
```

```
       tools directly or by external tooling provided by the distributions.

       lxc.start.auto
              Whether the container should be auto-started.  Valid values
              are 0 (off) and 1 (on).

       lxc.start.delay
              How long to wait (in seconds) after the container is started
              before starting the next one.

       lxc.start.order
              An integer used to sort the containers when auto-starting a
              series of containers at once.

       lxc.group
              A multi-value key (can be used multiple times) to put the
              container in a container group. Those groups can then be used
              (amongst other things) to start a series of related
              containers.

EXAMPLES

       In addition to the few examples given below, you will find some other
       examples of configuration file in /usr/local/share/doc/lxc/examples

   NETWORK
       This configuration sets up a container to use a veth pair device with
       one side plugged to a bridge br0 (which has been configured before on
       the system by the administrator). The virtual network device visible
       in the container is renamed to eth0.

            lxc.utsname = myhostname
            lxc.network.type = veth
            lxc.network.flags = up
            lxc.network.link = br0
            lxc.network.name = eth0
            lxc.network.hwaddr = 4a:49:43:49:79:bf
            lxc.network.ipv4 = 10.2.3.5/24 10.2.3.255
            lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3597

   UID/GID MAPPING
       This configuration will map both user and group ids in the range
       0-9999 in the container to the ids 100000-109999 on the host.

            lxc.id_map = u 0 100000 10000
            lxc.id_map = g 0 100000 10000

   CONTROL GROUP
       This configuration will setup several control groups for the
       application, cpuset.cpus restricts usage of the defined cpu,
       cpus.share prioritize the control group, devices.allow makes usable
       the specified devices.

            lxc.cgroup.cpuset.cpus = 0,1
            lxc.cgroup.cpu.shares = 1234
            lxc.cgroup.devices.deny = a
            lxc.cgroup.devices.allow = c 1:3 rw
            lxc.cgroup.devices.allow = b 8:0 rw

   COMPLEX CONFIGURATION
```

```
       This example show a complex configuration making a complex network
       stack, using the control groups, setting a new hostname, mounting
       some locations and a changing root file system.

            lxc.utsname = complex
            lxc.network.type = veth
            lxc.network.flags = up
            lxc.network.link = br0
            lxc.network.hwaddr = 4a:49:43:49:79:bf
            lxc.network.ipv4 = 10.2.3.5/24 10.2.3.255
            lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3597
            lxc.network.ipv6 = 2003:db8:1:0:214:5432:feab:3588
            lxc.network.type = macvlan
            lxc.network.flags = up
            lxc.network.link = eth0
            lxc.network.hwaddr = 4a:49:43:49:79:bd
            lxc.network.ipv4 = 10.2.3.4/24
            lxc.network.ipv4 = 192.168.10.125/24
            lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3596
            lxc.network.type = phys
            lxc.network.flags = up
            lxc.network.link = dummy0
            lxc.network.hwaddr = 4a:49:43:49:79:ff
            lxc.network.ipv4 = 10.2.3.6/24
            lxc.network.ipv6 = 2003:db8:1:0:214:1234:fe0b:3297
            lxc.cgroup.cpuset.cpus = 0,1
            lxc.cgroup.cpu.shares = 1234
            lxc.cgroup.devices.deny = a
            lxc.cgroup.devices.allow = c 1:3 rw
            lxc.cgroup.devices.allow = b 8:0 rw
            lxc.mount = /etc/fstab.complex
            lxc.mount.entry = /lib /root/myrootfs/lib none ro,bind 0 0
            lxc.rootfs = /mnt/rootfs.complex
            lxc.cap.drop = sys_module mknod setuid net_raw
            lxc.cap.drop = mac_override

```

The text below comes from the lxc.system.conf.5 man page:

```
LXC.SYSTEM.CONF(5)                                          LXC.SYSTEM.CONF(5)
NAME

       lxc.system.conf - LXC system configuration file

DESCRIPTION

       The system configuration is located at /usr/local/etc/lxc/lxc.conf or
       ~/.config/lxc/lxc.conf for unprivileged containers.

       This configuration file is used to set values such as default lookup
       paths and storage backend settings for LXC.

   CONFIGURATION PATHS
       lxc.lxcpath
              The location in which all containers are stored.

       lxc.default_config
              The path to the default container configuration.

   CONTROL GROUPS
       lxc.cgroup.use
              Comma separated list of cgroup controllers to setup.

       lxc.cgroup.pattern
              Format string used to generate the cgroup path (e.g. lxc/%n).

   LVM
       lxc.bdev.lvm.vg
              Default LVM volume group name.

       lxc.bdev.lvm.thin_pool
              Default LVM thin pool name.

   ZFS
       lxc.bdev.zfs.root
              Default ZFS root name.

1. Control Groups
=================

1.1 What are cgroups ?
----------------------

Control Groups provide a mechanism for aggregating/partitioning sets of
tasks, and all their future children, into hierarchical groups with
```

```
specialized behaviour.

Definitions:

A *cgroup* associates a set of tasks with a set of parameters for one
or more subsystems.

A *subsystem* is a module that makes use of the task grouping
facilities provided by cgroups to treat groups of tasks in
particular ways. A subsystem is typically a "resource controller" that
schedules a resource or applies per-cgroup limits, but it may be
anything that wants to act on a group of processes, e.g. a
virtualization subsystem.

A *hierarchy* is a set of cgroups arranged in a tree, such that
every task in the system is in exactly one of the cgroups in the
hierarchy, and a set of subsystems; each subsystem has system-specific
state attached to each cgroup in the hierarchy.  Each hierarchy has
an instance of the cgroup virtual filesystem associated with it.

At any one time there may be multiple active hierarchies of task
cgroups. Each hierarchy is a partition of all tasks in the system.

User-level code may create and destroy cgroups by name in an
instance of the cgroup virtual file system, specify and query to
which cgroup a task is assigned, and list the task PIDs assigned to
a cgroup. Those creations and assignments only affect the hierarchy
associated with that instance of the cgroup file system.

On their own, the only use for cgroups is for simple job
tracking. The intention is that other subsystems hook into the generic
cgroup support to provide new attributes for cgroups, such as
accounting/limiting the resources which processes in a cgroup can
access. For example, cpusets (see Documentation/cgroups/cpusets.txt) allow
you to associate a set of CPUs and a set of memory nodes with the
tasks in each cgroup.

1.2 Why are cgroups needed ?
----------------------------

There are multiple efforts to provide process aggregations in the
Linux kernel, mainly for resource-tracking purposes. Such efforts
include cpusets, CKRM/ResGroups, UserBeanCounters, and virtual server
namespaces. These all require the basic notion of a
grouping/partitioning of processes, with newly forked processes ending
up in the same group (cgroup) as their parent process.

The kernel cgroup patch provides the minimum essential kernel
mechanisms required to efficiently implement such groups. It has
minimal impact on the system fast paths, and provides hooks for
specific subsystems such as cpusets to provide additional behaviour as
desired.

Multiple hierarchy support is provided to allow for situations where
the division of tasks into cgroups is distinctly different for
different subsystems - having parallel hierarchies allows each
hierarchy to be a natural division of tasks, without having to handle
complex combinations of tasks that would be present if several
unrelated subsystems needed to be forced into the same tree of
cgroups.
```

```
At one extreme, each resource controller or subsystem could be in a
separate hierarchy; at the other extreme, all subsystems
would be attached to the same hierarchy.

As an example of a scenario (originally proposed by vatsa@in.ibm.com)
that can benefit from multiple hierarchies, consider a large
university server with various users - students, professors, system
tasks etc. The resource planning for this server could be along the
following lines:

       CPU :          "Top cpuset"
                       /       \
                CPUSet1         CPUSet2
                   |               |
                (Professors)    (Students)

                In addition (system tasks) are attached to topcpuset (so
                that they can run anywhere) with a limit of 20%

       Memory : Professors (50%), Students (30%), system (20%)

       Disk : Professors (50%), Students (30%), system (20%)

       Network : WWW browsing (20%), Network File System (60%), others (20%)
                                / \
                Professors (15%)  students (5%)

Browsers like Firefox/Lynx go into the WWW network class, while (k)nfsd goes
into the NFS network class.

At the same time Firefox/Lynx will share an appropriate CPU/Memory class
depending on who launched it (prof/student).

With the ability to classify tasks differently for different resources
(by putting those resource subsystems in different hierarchies),
the admin can easily set up a script which receives exec notifications
and depending on who is launching the browser he can

    # echo browser_pid > /sys/fs/cgroup/<restype>/<userclass>/tasks

With only a single hierarchy, he now would potentially have to create
a separate cgroup for every browser launched and associate it with
appropriate network and other resource class.  This may lead to
proliferation of such cgroups.

Also let's say that the administrator would like to give enhanced network
access temporarily to a student's browser (since it is night and the user
wants to do online gaming :))  OR give one of the student's simulation
apps enhanced CPU power.

With ability to write PIDs directly to resource classes, it's just a
matter of:

       # echo pid > /sys/fs/cgroup/network/<new_class>/tasks
       (after some time)
       # echo pid > /sys/fs/cgroup/network/<orig_class>/tasks

Without this ability, the administrator would have to split the cgroup into
multiple separate ones and then associate the new cgroups with the
```

```
new resource classes.

1.3 How are cgroups implemented ?
---------------------------------

Control Groups extends the kernel as follows:

 - Each task in the system has a reference-counted pointer to a
   css_set.

 - A css_set contains a set of reference-counted pointers to
   cgroup_subsys_state objects, one for each cgroup subsystem
   registered in the system. There is no direct link from a task to
   the cgroup of which it's a member in each hierarchy, but this
   can be determined by following pointers through the
   cgroup_subsys_state objects. This is because accessing the
   subsystem state is something that's expected to happen frequently
   and in performance-critical code, whereas operations that require a
   task's actual cgroup assignments (in particular, moving between
   cgroups) are less common. A linked list runs through the cg_list
   field of each task_struct using the css_set, anchored at
   css_set->tasks.

 - A cgroup hierarchy filesystem can be mounted for browsing and
   manipulation from user space.

 - You can list all the tasks (by PID) attached to any cgroup.

The implementation of cgroups requires a few, simple hooks
into the rest of the kernel, none in performance-critical paths:

 - in init/main.c, to initialize the root cgroups and initial
   css_set at system boot.

 - in fork and exit, to attach and detach a task from its css_set.

In addition, a new file system of type "cgroup" may be mounted, to
enable browsing and modifying the cgroups presently known to the
kernel.  When mounting a cgroup hierarchy, you may specify a
comma-separated list of subsystems to mount as the filesystem mount
options.  By default, mounting the cgroup filesystem attempts to
mount a hierarchy containing all registered subsystems.

If an active hierarchy with exactly the same set of subsystems already
exists, it will be reused for the new mount. If no existing hierarchy
matches, and any of the requested subsystems are in use in an existing
hierarchy, the mount will fail with -EBUSY. Otherwise, a new hierarchy
is activated, associated with the requested subsystems.

It's not currently possible to bind a new subsystem to an active
cgroup hierarchy, or to unbind a subsystem from an active cgroup
hierarchy. This may be possible in future, but is fraught with nasty
error-recovery issues.

When a cgroup filesystem is unmounted, if there are any
child cgroups created below the top-level cgroup, that hierarchy
will remain active even though unmounted; if there are no
child cgroups then the hierarchy will be deactivated.
```

```
No new system calls are added for cgroups - all support for
querying and modifying cgroups is via this cgroup file system.

Each task under /proc has an added file named 'cgroup' displaying,
for each active hierarchy, the subsystem names and the cgroup name
as the path relative to the root of the cgroup file system.

Each cgroup is represented by a directory in the cgroup file system
containing the following files describing that cgroup:

 - tasks: list of tasks (by PID) attached to that cgroup.  This list
   is not guaranteed to be sorted.  Writing a thread ID into this file
   moves the thread into this cgroup.
 - cgroup.procs: list of thread group IDs in the cgroup.  This list is
   not guaranteed to be sorted or free of duplicate TGIDs, and userspace
   should sort/uniquify the list if this property is required.
   Writing a thread group ID into this file moves all threads in that
   group into this cgroup.
 - notify_on_release flag: run the release agent on exit?
 - release_agent: the path to use for release notifications (this file
   exists in the top cgroup only)

Other subsystems such as cpusets may add additional files in each
cgroup dir.

New cgroups are created using the mkdir system call or shell
command.  The properties of a cgroup, such as its flags, are
modified by writing to the appropriate file in that cgroups
directory, as listed above.

The named hierarchical structure of nested cgroups allows partitioning
a large system into nested, dynamically changeable, "soft-partitions".

The attachment of each task, automatically inherited at fork by any
children of that task, to a cgroup allows organizing the work load
on a system into related sets of tasks.  A task may be re-attached to
any other cgroup, if allowed by the permissions on the necessary
cgroup file system directories.

When a task is moved from one cgroup to another, it gets a new
css_set pointer - if there's an already existing css_set with the
desired collection of cgroups then that group is reused, otherwise a new
css_set is allocated. The appropriate existing css_set is located by
looking into a hash table.

To allow access from a cgroup to the css_sets (and hence tasks)
that comprise it, a set of cg_cgroup_link objects form a lattice;
each cg_cgroup_link is linked into a list of cg_cgroup_links for
a single cgroup on its cgrp_link_list field, and a list of
cg_cgroup_links for a single css_set on its cg_link_list.

Thus the set of tasks in a cgroup can be listed by iterating over
each css_set that references the cgroup, and sub-iterating over
each css_set's task set.

The use of a Linux virtual file system (vfs) to represent the
cgroup hierarchy provides for a familiar permission and name space
for cgroups, with a minimum of additional kernel code.
```

```
1.4 What does notify_on_release do ?
------------------------------------

If the notify_on_release flag is enabled (1) in a cgroup, then
whenever the last task in the cgroup leaves (exits or attaches to
some other cgroup) and the last child cgroup of that cgroup
is removed, then the kernel runs the command specified by the contents
of the "release_agent" file in that hierarchy's root directory,
supplying the pathname (relative to the mount point of the cgroup
file system) of the abandoned cgroup.  This enables automatic
removal of abandoned cgroups.  The default value of
notify_on_release in the root cgroup at system boot is disabled
(0).  The default value of other cgroups at creation is the current
value of their parents' notify_on_release settings. The default value of
a cgroup hierarchy's release_agent path is empty.

1.5 What does clone_children do ?
---------------------------------

This flag only affects the cpuset controller. If the clone_children
flag is enabled (1) in a cgroup, a new cpuset cgroup will copy its
configuration from the parent during initialization.

1.6 How do I use cgroups ?
--------------------------

To start a new job that is to be contained within a cgroup, using
the "cpuset" cgroup subsystem, the steps are something like:

 1) mount -t tmpfs cgroup_root /sys/fs/cgroup
 2) mkdir /sys/fs/cgroup/cpuset
 3) mount -t cgroup -ocpuset cpuset /sys/fs/cgroup/cpuset
 4) Create the new cgroup by doing mkdir's and write's (or echo's) in
    the /sys/fs/cgroup virtual file system.
 5) Start a task that will be the "founding father" of the new job.
 6) Attach that task to the new cgroup by writing its PID to the
    /sys/fs/cgroup/cpuset/tasks file for that cgroup.
 7) fork, exec or clone the job tasks from this founding father task.

For example, the following sequence of commands will setup a cgroup
named "Charlie", containing just CPUs 2 and 3, and Memory Node 1,
and then start a subshell 'sh' in that cgroup:

  mount -t tmpfs cgroup_root /sys/fs/cgroup
  mkdir /sys/fs/cgroup/cpuset
  mount -t cgroup cpuset -ocpuset /sys/fs/cgroup/cpuset
  cd /sys/fs/cgroup/cpuset
  mkdir Charlie
  cd Charlie
  /bin/echo 2-3 > cpuset.cpus
  /bin/echo 1 > cpuset.mems
  /bin/echo $$ > tasks
  sh
  # The subshell 'sh' is now running in cgroup Charlie
  # The next line should display '/Charlie'
  cat /proc/self/cgroup

2. Usage Examples and Syntax
============================
```

```
2.1 Basic Usage
---------------

Creating, modifying, using cgroups can be done through the cgroup
virtual filesystem.

To mount a cgroup hierarchy with all available subsystems, type:
# mount -t cgroup xxx /sys/fs/cgroup

The "xxx" is not interpreted by the cgroup code, but will appear in
/proc/mounts so may be any useful identifying string that you like.

Note: Some subsystems do not work without some user input first.  For instance,
if cpusets are enabled the user will have to populate the cpus and mems files
for each new cgroup created before that group can be used.

As explained in section `1.2 Why are cgroups needed?' you should create
different hierarchies of cgroups for each single resource or group of
resources you want to control. Therefore, you should mount a tmpfs on
/sys/fs/cgroup and create directories for each cgroup resource or resource
group.

# mount -t tmpfs cgroup_root /sys/fs/cgroup
# mkdir /sys/fs/cgroup/rg1

To mount a cgroup hierarchy with just the cpuset and memory
subsystems, type:
# mount -t cgroup -o cpuset,memory hier1 /sys/fs/cgroup/rg1

While remounting cgroups is currently supported, it is not recommend
to use it. Remounting allows changing bound subsystems and
release_agent. Rebinding is hardly useful as it only works when the
hierarchy is empty and release_agent itself should be replaced with
conventional fsnotify. The support for remounting will be removed in
the future.

To Specify a hierarchy's release_agent:
# mount -t cgroup -o cpuset,release_agent="/sbin/cpuset_release_agent" \
  xxx /sys/fs/cgroup/rg1

Note that specifying 'release_agent' more than once will return failure.

Note that changing the set of subsystems is currently only supported
when the hierarchy consists of a single (root) cgroup. Supporting
the ability to arbitrarily bind/unbind subsystems from an existing
cgroup hierarchy is intended to be implemented in the future.

Then under /sys/fs/cgroup/rg1 you can find a tree that corresponds to the
tree of the cgroups in the system. For instance, /sys/fs/cgroup/rg1
is the cgroup that holds the whole system.

If you want to change the value of release_agent:
# echo "/sbin/new_release_agent" > /sys/fs/cgroup/rg1/release_agent

It can also be changed via remount.

If you want to create a new cgroup under /sys/fs/cgroup/rg1:
# cd /sys/fs/cgroup/rg1
# mkdir my_cgroup
```

```
Now you want to do something with this cgroup.
# cd my_cgroup

In this directory you can find several files:
# ls
cgroup.procs notify_on_release tasks
(plus whatever files added by the attached subsystems)

Now attach your shell to this cgroup:
# /bin/echo $$ > tasks

You can also create cgroups inside your cgroup by using mkdir in this
directory.
# mkdir my_sub_cs

To remove a cgroup, just use rmdir:
# rmdir my_sub_cs

This will fail if the cgroup is in use (has cgroups inside, or
has processes attached, or is held alive by other subsystem-specific
reference).

2.2 Attaching processes
-----------------------

# /bin/echo PID > tasks

Note that it is PID, not PIDs. You can only attach ONE task at a time.
If you have several tasks to attach, you have to do it one after another:

# /bin/echo PID1 > tasks
# /bin/echo PID2 > tasks
    ...
# /bin/echo PIDn > tasks

You can attach the current shell task by echoing 0:

# echo 0 > tasks

You can use the cgroup.procs file instead of the tasks file to move all
threads in a threadgroup at once. Echoing the PID of any task in a
threadgroup to cgroup.procs causes all tasks in that threadgroup to be
attached to the cgroup. Writing 0 to cgroup.procs moves all tasks
in the writing task's threadgroup.

Note: Since every task is always a member of exactly one cgroup in each
mounted hierarchy, to remove a task from its current cgroup you must
move it into a new cgroup (possibly the root cgroup) by writing to the
new cgroup's tasks file.

Note: Due to some restrictions enforced by some cgroup subsystems, moving
a process to another cgroup can fail.

2.3 Mounting hierarchies by name
--------------------------------

Passing the name=<x> option when mounting a cgroups hierarchy
associates the given name with the hierarchy.  This can be used when
mounting a pre-existing hierarchy, in order to refer to it by name
rather than by its set of active subsystems.  Each hierarchy is either
```

```
nameless, or has a unique name.

The name should match [\w.-]+

When passing a name=<x> option for a new hierarchy, you need to
specify subsystems manually; the legacy behaviour of mounting all
subsystems when none are explicitly specified is not supported when
you give a subsystem a name.

The name of the subsystem appears as part of the hierarchy description
in /proc/mounts and /proc/<pid>/cgroups.

3. Kernel API
=============

3.1 Overview
------------

Each kernel subsystem that wants to hook into the generic cgroup
system needs to create a cgroup_subsys object. This contains
various methods, which are callbacks from the cgroup system, along
with a subsystem ID which will be assigned by the cgroup system.

Other fields in the cgroup_subsys object include:

- subsys_id: a unique array index for the subsystem, indicating which
  entry in cgroup->subsys[] this subsystem should be managing.

- name: should be initialized to a unique subsystem name. Should be
  no longer than MAX_CGROUP_TYPE_NAMELEN.

- early_init: indicate if the subsystem needs early initialization
  at system boot.

Each cgroup object created by the system has an array of pointers,
indexed by subsystem ID; this pointer is entirely managed by the
subsystem; the generic cgroup code will never touch this pointer.

3.2 Synchronization
-------------------

There is a global mutex, cgroup_mutex, used by the cgroup
system. This should be taken by anything that wants to modify a
cgroup. It may also be taken to prevent cgroups from being
modified, but more specific locks may be more appropriate in that
situation.

See kernel/cgroup.c for more details.

Subsystems can take/release the cgroup_mutex via the functions
cgroup_lock()/cgroup_unlock().

Accessing a task's cgroup pointer may be done in the following ways:
- while holding cgroup_mutex
- while holding the task's alloc_lock (via task_lock())
- inside an rcu_read_lock() section via rcu_dereference()

3.3 Subsystem API
-----------------
```

```
Each subsystem should:

- add an entry in linux/cgroup_subsys.h
- define a cgroup_subsys object called <name>_subsys

If a subsystem can be compiled as a module, it should also have in its
module initcall a call to cgroup_load_subsys(), and in its exitcall a
call to cgroup_unload_subsys(). It should also set its_subsys.module =
THIS_MODULE in its .c file.

Each subsystem may export the following methods. The only mandatory
methods are css_alloc/free. Any others that are null are presumed to
be successful no-ops.

struct cgroup_subsys_state *css_alloc(struct cgroup *cgrp)
(cgroup_mutex held by caller)

Called to allocate a subsystem state object for a cgroup. The
subsystem should allocate its subsystem state object for the passed
cgroup, returning a pointer to the new object on success or a
ERR_PTR() value. On success, the subsystem pointer should point to
a structure of type cgroup_subsys_state (typically embedded in a
larger subsystem-specific object), which will be initialized by the
cgroup system. Note that this will be called at initialization to
create the root subsystem state for this subsystem; this case can be
identified by the passed cgroup object having a NULL parent (since
it's the root of the hierarchy) and may be an appropriate place for
initialization code.

int css_online(struct cgroup *cgrp)
(cgroup_mutex held by caller)

Called after @cgrp successfully completed all allocations and made
visible to cgroup_for_each_child/descendant_*() iterators. The
subsystem may choose to fail creation by returning -errno. This
callback can be used to implement reliable state sharing and
propagation along the hierarchy. See the comment on
cgroup_for_each_descendant_pre() for details.

void css_offline(struct cgroup *cgrp);
(cgroup_mutex held by caller)

This is the counterpart of css_online() and called iff css_online()
has succeeded on @cgrp. This signifies the beginning of the end of
@cgrp. @cgrp is being removed and the subsystem should start dropping
all references it's holding on @cgrp. When all references are dropped,
cgroup removal will proceed to the next step - css_free(). After this
callback, @cgrp should be considered dead to the subsystem.

void css_free(struct cgroup *cgrp)
(cgroup_mutex held by caller)

The cgroup system is about to free @cgrp; the subsystem should free
its subsystem state object. By the time this method is called, @cgrp
is completely unused; @cgrp->parent is still valid. (Note - can also
be called for a newly-created cgroup if an error occurs after this
subsystem's create() method has been called for the new cgroup).

int can_attach(struct cgroup *cgrp, struct cgroup_taskset *tset)
```

```
(cgroup_mutex held by caller)

Called prior to moving one or more tasks into a cgroup; if the
subsystem returns an error, this will abort the attach operation.
@tset contains the tasks to be attached and is guaranteed to have at
least one task in it.

If there are multiple tasks in the taskset, then:
  - it's guaranteed that all are from the same thread group
  - @tset contains all tasks from the thread group whether or not
    they're switching cgroups
  - the first task is the leader

Each @tset entry also contains the task's old cgroup and tasks which
aren't switching cgroup can be skipped easily using the
cgroup_taskset_for_each() iterator. Note that this isn't called on a
fork. If this method returns 0 (success) then this should remain valid
while the caller holds cgroup_mutex and it is ensured that either
attach() or cancel_attach() will be called in future.

void cancel_attach(struct cgroup *cgrp, struct cgroup_taskset *tset)
(cgroup_mutex held by caller)

Called when a task attach operation has failed after can_attach() has succeeded.
A subsystem whose can_attach() has some side-effects should provide this
function, so that the subsystem can implement a rollback. If not, not necessary.
This will be called only about subsystems whose can_attach() operation have
succeeded. The parameters are identical to can_attach().

void attach(struct cgroup *cgrp, struct cgroup_taskset *tset)
(cgroup_mutex held by caller)

Called after the task has been attached to the cgroup, to allow any
post-attachment activity that requires memory allocations or blocking.
The parameters are identical to can_attach().

void fork(struct task_struct *task)

Called when a task is forked into a cgroup.

void exit(struct task_struct *task)

Called during task exit.

void bind(struct cgroup *root)
(cgroup_mutex held by caller)

Called when a cgroup subsystem is rebound to a different hierarchy
and root cgroup. Currently this will only involve movement between
the default hierarchy (which never has sub-cgroups) and a hierarchy
that is being created/destroyed (and hence has no sub-cgroups).

4. Extended attribute usage
===========================

cgroup filesystem supports certain types of extended attributes in its
directories and files.  The current supported types are:
    - Trusted (XATTR_TRUSTED)
    - Security (XATTR_SECURITY)
```

```
Both require CAP_SYS_ADMIN capability to set.

Like in tmpfs, the extended attributes in cgroup filesystem are stored
using kernel memory and it's advised to keep the usage at minimum.  This
is the reason why user defined extended attributes are not supported, since
any user can do it and there's no limit in the value size.

The current known users for this feature are SELinux to limit cgroup usage
in containers and systemd for assorted meta data like main PID in a cgroup
(systemd creates a cgroup per service).

5. Questions
============

Q: what's up with this '/bin/echo' ?
A: bash's builtin 'echo' command does not check calls to write() against
   errors. If you use it in the cgroup file system, you won't be
   able to tell whether a command succeeded or failed.

Q: When I attach processes, only the first of the line gets really attached !
A: We can only return one error code per call to write(). So you should also
   put only ONE PID.
```

11.5 Docker Containers

11.5.1 Introduction to Docker Containers

11.5.1.1 Overview

This section is a guide and tutorial to building and using Docker Containers. Docker Containers are only available on ARM64 platforms, with the exception of LS1043 Big Endian.

Docker is a different set of userspace tools implementing Linux containers and focusing on a different set of use cases. The highlights of this open source project are ease of use, shared contributions and fast deployment. In the Docker ecosystem, containers are application environment packages, which can be easily distributed and developed collaboratively, and are guaranteed to be reproducible on any supporting platform, from the development stage to production. Currently, Docker containers are mainly targeting cloud environments.

Docker can be viewed as a set of separate components:

- **Images** - the "build" component of Docker. These are read-only copies of container root filesystems, consisting of the designed application and it's userspace dependencies. For example, an image can contain an Ubuntu application, an Apache server and a user web app. This image can be used to get a webserver running.
- **Registries** - the "distribution" component of Docker. These are public or private stores where users can upload / download images. The images are versioned, and are built from layers. When sharing images, the layers are first downloaded separately, and the image is assembled at runtime. Each layer corresponds to a specific user commit. Images can also be built using buildfiles. The most representative registry example is the Docker Hub. The current Docker installation does not support registry configuration.
- **Containers** - the "run" component of Docker. These are very similar to the containers provided by the LXC package. The main difference is that Docker containers use an overlay filesystem as container support. The layers are taken as is from the image and marked read-only, with a topmost read-write layer on top. This means that no container makes any persistent changes to the image by default - these need to be explicitly committed by the user when the environment is in the desired state. Docker containers are designed to work as application containers by default.

Docker uses a client-server architecture. The client takes the user commands and talks to a daemon, which does the entire container management work. A Linux host running the daemon is called a Docker Host. The client and daemon can run on the same machine, or on different ones, communicating through sockets or a RESTful API.

The Docker official page advertises a set of use cases, mostly relevant in cloud environments: continuous integration, continuous delivery, devops, big data and infrastructure optimization. These can be easily adapted to embedded distributions as well. As for the containers themselves, the Linux Containers chapter use cases apply, with a focus on ease of use, fast deployment and distributed usage.

11.5.2 Build and Installation

11.5.2.1 Building with Yocto

Docker is a Linux user space package that can easily be added to a rootfs using the Yocto build system.

In the NXP SDK, Docker and all pre-requisite user space packages are included when building the "virt" image type:

```
bitbake fsl-image-virt
```

Docker can be easily added to any rootfs image by updating the `IMAGE_INSTALL_append` variable in the conf/local.conf file in the Yocto build environment. For example, append the following line to local.conf:

```
IMAGE_INSTALL_append = " docker docker-registry"
```

If you are building for ARM64 platforms, you need to perform an additional step. You need to update the rootfs target in the board image - by default it is fsl-image-core. If you plan to update this rootfs to, say, fsl-image-virt, you need to add the following line in to build_<machine_release>/conf/local.conf:

```
ROOTFS_IMAGE = "fsl-image-virt”
```

After enabling the required Linux options mentioned in the following chapter, generate the kernel itb:

```
bitbake fsl-image-kernelitb
```

11.5.2.2 Building the Linux Kernel

In order to use Docker, the Linux kernel must be configured with the options required by LXC containers, and some others that are specific to the filesystem overlay and Docker's internal networking.

These options can be enabled automatically by building the Linux kernel with an additional config fragment. In order to do this, add the following line in the **conf/local.conf** file in the Yocto build environment:

```
DELTA_KERNEL_DEFCONFIG_append = " <sdk-devel>/sources/meta-freescale/recipes-kernel/linux/files/
containers.config"
```

Alternatively, you can enable the options manually. Please make sure you have enabled the options required by LXC containers first. To configure and build the Linux kernel:

```
bitbake virtual/kernel -c cleansstate
bitbake virtual/kernel -c menuconfig
bitbake virtual/kernel
```

Make sure that the following options are also enabled (besides the ones mentioned in the LXC chapter):

```
[*] Networking support  --->
  Networking options  --->
    [*] TCP/IP networking
    < >   The IPv6 protocol
    [*] Network packet filtering framework (Netfilter)  --->
      Core Netfilter Configuration  --->

11.5.3 Docker How To's

11.5.3.1 Running a webserver container

The following article describes the necessary steps to deploy a web server service using a Docker container. This is based on downloading a prepared image from the Docker hub and using it to start a container.

1. Make sure you have sufficient space on the underlying filesystem where `/var/lib` resides. In the test setup, the root filesystem is mounted on a small flash memory, not sufficient for downloading the Docker image. Therefore, `/var/lib` is transferred to a RAM filesystem mount.

   ```
   # Docker - temporary /var/lib mount
   mkdir ~/var_lib
   cp -R /var/lib/* ~/var_lib
   ```

```
mount -t tmpfs var_lib_tmpfs /var/lib
cp -R ~/var_lib/* /var/lib/
```

2. Start the docker daemon. Make sure that the board has Internet access - this will be required to download the image from the Docker Hub. The daemon will configure a Linux bridge for the containers with a private network and NAT.

```
:~# docker daemon
ERRO[0000] Failed to built-in GetDriver graph btrfs /var/lib/docker
ERRO[0000] Failed to built-in GetDriver graph devicemapper /var/lib/docker
INFO[0000] API listen on /var/run/docker.sock
INFO[0000] Default bridge (docker0) is assigned with an IP address 172.17.0.0/16. Daemon option
--bip can be used to set a preferred IP address
INFO[0000] Loading containers: start.

INFO[0000] Loading containers: done.
INFO[0000] Daemon has completed initialization
INFO[0000] Docker daemon                                 commit=7e5506d-dirty
execdriver=native-0.2 graphdriver=overlay version=1.9.0
```

3. You can search the registry for available **arm64** images, or using any other keyword.

```
:~# docker search arm64

```

4. In this example, `qoriq/arm64-ubuntu` is used. It's a standard Ubuntu compiled for ARM64, with a lighttpd webserver installed and with a home page configured to display some information on the LS2085A boards, processes and networking in the container. First download the image.

```
:~# docker pull qoriq/arm64-ubuntu
Using default tag: latest
latest: Pulling from qoriq/arm64-ubuntu

Digest: sha256:eaef3a08336f59155e6cfb61bf55688711214561ddf00817b5c848211ac66b00
Status: Downloaded newer image for qoriq/arm64-ubuntu:latest
```

You can check the image is available using `docker images`:

```
:~# docker images
REPOSITORY          TAG                 IMAGE ID            CREATED             VIRTUAL SIZE
qoriq/arm64-ubuntu  latest              885db99879a8        59 minutes ago      326.4 MB
```

5. Start a container using the following command:

```
:~# docker run -d -p 30081:80 --name=sandbox1 -h sandbox1 qoriq/arm64-ubuntu bash -c "lighttpd -
f /etc/lighttpd/lighttpd.conf -D"
468a1e4c474414379cd0dab810a7883d8037db4795b3287526ad051741ef2525
```

- `run` - create and start the container. Optionally, download the image if not available on the host.
- `-d` - start the container as a daemon.
- `-p 30081:80` - forward port 80 in the container to port 30081 on the board.
- `--name=sandbox1` - the name of the container (as visible to Docker).
- `-h sandbox1` - the hostname inside the container.
- `qoriq/arm64-ubuntu` - the base image for the container.
- `bash -c "lighttpd -f /etc/lighttpd/lighttpd.conf -D"` - the command to execute as PID 1 in the container.

The command will return a unique SHA for the container. You can check that the webserver is up and running by accessing `http://BOARD_IP:30081/` from a browser. You can also check the container is running using docker:

```
:~# docker ps -a
CONTAINER ID        IMAGE                      COMMAND                  CREATED
STATUS              PORTS                   NAMES
468a1e4c4744        qoriq/arm64-ubuntu         "bash -c 'lighttpd -f"   About a minute ago
Up About a minute   0.0.0.0:30081->80/tcp   sandbox1
```

6. Stopping and deleting the container are easy operations:

```
:~# docker stop sandbox1
sandbox1
:~# docker rm sandbox1
sandbox1
```

7. A similar command can be used to delete the image from the board.

```
:~# docker rmi qoriq/arm64-ubuntu

11.6 User Space DPDK with OVS & Virtio Devices

For more information on using OVS-DPDK in user space with VIRTIO interfaces, refer to OVS-DPDK and DPDK in VM with VIRTIO Interfaces on page 1333.

Chapter 12
Benchmark Reproducibility Guides

12.1 Linux Core

Linux Core - Benchmark Reproducibility Guides

12.1.1 Coremark

How to setup a board to baseline Coremark performance for QorIQ processor development boards.

12.1.1.1 Test Environment

Objectives

The first objective is to baseline the Coremark performance on QorIQ platform. Next identify any optimizations that have been discovered and ensure they are implemented on the those platforms. Investigate other changes that may improve performance.

Hardware Platform Identification

Table 594. Target Platform

Board	Silicon Revision	Default Freqeuncy(Core/CCB/DDR) in MHz	Core Type
P2040RDB	Rev2.0	1200/600/1200	e500mc
P3041DS	Rev2.0	1500/750/1333	e500mc

LS1043ARDB	Rev1.0	1600/400/1600	cortex A53
LS2080ARDB	Rev1.0	1867/533/1867	cortex A57

For board switch settings, please see to the corresponding reference manual.

Software Platform Identification

All software was built from QorIQ SDK ISO.

Boot Loader

U-boot 2016.01 with NXP-specific patches on top;

Coremark Application

Source Code Download

Coremark Source code can be downloaded from www.coremark.org

Toolchain version is gcc-4.9.2 with glibc-2.21 for SDK v2.0

Build coremark

1. If you are compiling CoreMark on 64 bit linux machine (machine on which you have the intended compiler) go to coremark_v1.0/linux64 directory, else go to coremark_v1.0/linux directory
2. Give the complete compiler path under "CC" flag in core_portme.mak file

```
For example: e6500 toolchain path of sdkv1.9:
CC = /opt/fsl-qoriq/1.9/sysroots/x86_64-fsl_networking_sdk-linux/usr/bin/powerpc-
fsl_networking-linux-gcc
```

3. Go back to coremark_v1.0 directory. Give following command on the command line
   - For e500mc:

```
make PORT_CFLAGS="-mcpu=e500mc -O3 -fipa-pta -funroll-all-loops -ftree-loop-ivcanon -
fvariable-expansion-in-unroller -fpeel-loops -floop-interchange --param max-inline-
insns-auto=1000 --param max-average-unrolled-insns=99999999 -fgcse-las -fgcse-after-
reload  -fwiden-types -static --sysroot=/opt/fsl-qoriq/2.0/sysroots/ppce500mc-fsl-
linux”
```

   - For e5500-32bit:

```
make PORT_CFLAGS="-mcpu=e5500 -m64 -mcmodel=small -O3 -fipa-pta -funroll-all-loops -
ftree-loop-ivcanon -fvariable-expansion-in-unroller -floop-block -fno-auto-inc-dec --
param max-inline-insns-auto=1000 --param max-average-unrolled-insns=99999999 --param
iv-max-considered-uses=9999999 -fno-ira-loop-pressure -fsched-pressure -fmodulo-sched
-fmodulo-sched-allow-regmoves -fwiden-types -fno-align-loops -static --sysroot=/opt/
fsl-qoriq/2.0/sysroots/ppc64e5500-fsl-linux”
```

   - For e5500-64bit:

```
make PORT_CFLAGS="-mcpu=e5500 -m64 -mcmodel=small -O3 -fipa-pta -funroll-all-loops -
ftree-loop-ivcanon -fvariable-expansion-in-unroller -floop-block -fno-auto-inc-dec --
param max-inline-insns-auto=1000 --param max-average-unrolled-insns=99999999 --param
iv-max-considered-uses=9999999 -fno-ira-loop-pressure -fsched-pressure -fmodulo-sched
-fmodulo-sched-allow-regmoves -fwiden-types -fno-align-loops -static --sysroot=/opt/
fsl-qoriq/2.0/sysroots/ppc64e5500-fsl-linux "
```

   - For e6500-32bit:

```
Single thread:
make PORT_CFLAGS="-mcpu=e6500 -m32 -O3 -finline-limit=99999 -fgcse-sm -fgcse-las  -
fopt-array-offset -frename-registers -fsched-spec-load -fsched-spec-load-dangerous -
funroll-all-loops -ftree-loop-ivcanon -fvariable-expansion-in-unroller -funsafe-loop-
optimizations -funswitch-loops -static --sysroot=/opt/fsl-qoriq/2.0/sysroots/ppce6500-
fsl-linux"
Multithread:
make PORT_CFLAGS="-mcpu=e6500 -m32 -O3 -finline-limit=99999 -fgcse-sm -fgcse-las  -
fopt-array-offset -frename-registers -fsched-spec-load -fsched-spec-load-dangerous -
funroll-all-loops -ftree-loop-ivcanon -fvariable-expansion-in-unroller -funsafe-loop-
```

```
optimizations -funswitch-loops -static --sysroot=/opt/fsl-qoriq/2.0/sysroots/ppce6500-
fsl-linux -DMULTITHREAD=2/4/8/16/24 -DUSE_FORK=1"
```

- For e6500-64bit:

```
Single thread:
make PORT_CFLAGS="-mcpu=e6500 -m64 -mcmodel=small -O3 -finline-limit=99999 -fsched-
pressure -funroll-all-loops -ftree-loop-ivcanon -fvariable-expansion-in-unroller -
funsafe-loop-optimizations --param max-average-unrolled-insns=99999999 --sysroot=/opt/
fsl-qoriq/2.0/sysroots/ppc64e6500-fsl-linux -static"
Multithread:
make PORT_CFLAGS="-mcpu=e6500 -m64 -mcmodel=small -O3 -finline-limit=99999 -fsched-
pressure -funroll-all-loops -ftree-loop-ivcanon -fvariable-expansion-in-unroller -
funsafe-loop-optimizations --param max-average-unrolled-insns=99999999 --sysroot=/opt/
fsl-qoriq/2.0/sysroots/ppc64e6500-fsl-linux -static -DMULTITHREAD=<2/4/8/12/16/20/24>
-DUSE_FORK=1"
```

- For cortex A53 (LS1043A)

```
Single thread:
make PORT_CFLAGS = "-mcpu=cortex-a53 -march=armv8-a+fp+simd+crc+crypto -O3 -funroll-
all-loops --param max-inline-insns-auto=550 --param case-values-threshold=30 -falign-
functions=32 -ftracer --sysroot=/opt/fsl-qoriq/2.0/sysroots/aarch64-fsl-linux"
Multithread:
make PORT_CFLAGS = "-mcpu=cortex-a53 -march=armv8-a+fp+simd+crc+crypto -O3 -funroll-
all-loops --param max-inline-insns-auto=550 --param case-values-threshold=30 -falign-
functions=32 -ftracer --sysroot=/opt/fsl-qoriq/2.0/sysroots/aarch64-fsl-linux -
DMULTITHREAD=4 -DUSE_FORK=1"
```

- For cortex A57 (LS2080A)

```
Single thread:
make PORT_CFLAGS = "-mcpu=cortex-a57 -march=armv8-a+fp+simd+crc+crypto -O3 -funroll-
all-loops --param max-inline-insns-auto=550 --param case-values-threshold=30 -falign-
functions=32 -ftracer --sysroot=/opt/fsl-qoriq/2.0/sysroots/aarch64-fsl-linux"
Multithread:
make PORT_CFLAGS = "-mcpu=cortex-a57 -march=armv8-a+fp+simd+crc+crypto -O3 -funroll-
all-loops --param max-inline-insns-auto=550 --param case-values-threshold=30 -falign-
functions=32 -ftracer --sysroot=/opt/fsl-qoriq/2.0/sysroots/aarch64-fsl-linux -
DMULTITHREAD=4 -DUSE_FORK=1"
```

- For cortex A7 (LS1021A and LS1043A/LS2080A 32bit)

```
Single thread:
make PORT_CFLAGS="-O3 -march=armv7-a -mfloat-abi=hard -mfpu=neon -mtune=cortex-a7 -
funroll-all-loops --param max-inline-insns-auto=300 -static --sysroot=/opt/fsl-
qoriq/2.0/sysroots/cortexa7hf-vfp-neon-fsl-linux-gnueabi"
Multithread:
make PORT_CFLAGS="-O3 -march=armv7-a -mfloat-abi=hard -mfpu=neon -mtune=cortex-a7 -
funroll-all-loops --param max-inline-insns-auto=300 -static --sysroot=/opt/fsl-
qoriq/2.0/sysroots/cortexa7hf-vfp-neon-fsl-linux-gnueabi -DMULTITHREAD=2 -DUSE_FORK=1"
```

4. The command will first compile, generate the executable file (coremark.exe) and try to run the benchmark. Transfer the executable file to the target

12.1.1.2 Test Procedure

Test procedure for lmbench.

Running test and result collection

Deploy target board with corresponding software mentioned in previous section.

Put coremark binary compiled with optimized flags mentioned in section test environment on target board

Run the benchmark

```
coremark.exe
```

and result will like as followings:

```
2K performance run parameters for coremark.
CoreMark Size    : 666
Total ticks      : 19508
Total time (secs): 19.508000
Iterations/Sec   : 5638.712323
Iterations       : 110000
Compiler version : GCC4.6.2

This test measures the variation of the benchmark results, so an average across 5 runs was taken for every result.

12.1.2 Dhrystone

How to setup a board to baseline Dhrystone performance for QorIQ processor development boards.

12.1.2.1 Test Environment

Objectives

The first objective is to baseline the Dhrystone performance on QorIQ platform. Next identify any optimizations that have been discovered and ensure they are implemented on the those platforms. Investigate other changes that may improve performance. Compare these results with other NXP and competitors products. Provide assistance to any customer activities that could result in design wins. Review the results with. Finally post the results and this guild so that groups within NXP may share them with customers.

Hardware Platform Identification

LS1021ATWR	Rev2.0	1000/300/1600	cortex A7

For board switch settings, please see to the corresponding reference manual.

Software Platform Identification

All software was built from QorIQ SDK ISO.

Boot Loader

U-boot 2016.01 with NXP-specific patches on top.

Dhrystone Application

Benchmark methodology

Dhrystone is a synthetic computing benchmark program intended to be representative of system (integer) programming. It is a simple program that is carefully designed to statistically mimic the processor usage of some common set of programs. It is also have some pills, for the performance will be affected by many factors such as the compiler, libraries and so on.

Source Code Download

Dhrystone 1.0 Source code can be downloaded from `http://www.xanthos.se/~joachim/vaxmips.html (Dhrystone-src.tar.gz)`

Toolchain version is gcc-4.9.2 with glibc-2.21 for SDK v2.0

Build source code

1. Download the source code from `http://www.xanthos.se/~joachim/vaxmips.html (Dhrystone-src.tar.gz)`
2. Unpack the package
3. Go back to dhrystone_v1.0 directory. Apply patches for different platform:
   - For e500v2:

     Please contact your sales representatives for this patch.
   - For e500mc and e5500 32bit:

Please contact your sales representatives for this patch.

- For e5500 64bit:

  Please contact your sales representatives for this patch.

- For e6500:

  Please contact your sales representatives for this patch.

- For e6500 64bit:

  Please contact your sales representatives for this patch.

- For LS1021A:

  Please contact your sales representatives for this patch.

The command will first compile, generate the executable file (dhrystone.exe) and try to run the benchmark. Transfer the executable file to the target.

12.1.2.2 Test Procedure

Test procedure for lmbench.

Running test and result collection

Deploy target board with corresponding software mentioned in previous section.

Put dhrystone binary compiled with optimized flags mentioned in section 2.2.2.3 on target board

Run the benchmark

```
echo 50000000 | ./dhrystone.exe
```

and result will like as followings:

```
Dhrystone Benchmark, Version 2.1 (Language: C)

Please give the number of runs through the benchmark:
Execution starts, 50000000 runs through Dhrystone
Execution ends

Final values of the variables used in the benchmark:

Int_Glob:            5
        should be:   5
Bool_Glob:           1
        should be:   1
Ch_1_Glob:           A
        should be:   A
Ch_2_Glob:           B
        should be:   B
Arr_1_Glob[8]:       7
        should be:   7
Arr_2_Glob[8][7]:    50000010
        should be:   Number_Of_Runs + 10
Ptr_Glob->
  Ptr_Comp:          268525944
        should be:   (implementation-dependent)
  Discr:             0
        should be:   0
  Enum_Comp:         2
        should be:   2
  Int_Comp:          17
        should be:   17
  Str_Comp:          DHRYSTONE PROGRAM, SOME STRING
        should be:   DHRYSTONE PROGRAM, SOME STRING
Next_Ptr_Glob->
```

```
  Ptr_Comp:          268525944
        should be:   (implementation-dependent), same as above
  Discr:             0
        should be:   0
  Enum_Comp:         1
        should be:   1
  Int_Comp:          18
        should be:   18
  Str_Comp:          DHRYSTONE PROGRAM, SOME STRING
        should be:   DHRYSTONE PROGRAM, SOME STRING
Int_1_Loc:           5
        should be:   5
Int_2_Loc:           13
        should be:   13
Int_3_Loc:           7
        should be:   7
Enum_Loc:            1
        should be:   1
Str_1_Loc:           DHRYSTONE PROGRAM, 1'ST STRING
        should be:   DHRYSTONE PROGRAM, 1'ST STRING
Str_2_Loc:           DHRYSTONE PROGRAM, 2'ND STRING
        should be:   DHRYSTONE PROGRAM, 2'ND STRING

Register option selected?  NO
Microseconds for one run through Dhrystone:     0.4
Dhrystones per Second:                       2689328.7
VAX MIPS rating =   1530.637
```

There is a run to run variation in benchmark result, so an average across 5 runs was taken for every result

12.1.3 EEMBC

How to setup a board to baseline EEMBC Netmark performance for QorIQ processor development boards.

12.1.3.1 Test Environment

Objectives

The first objective is to baseline the EEMBC Netmark performance on QorIQ platform. Next identify any optimizations that have been discovered and ensure they are implemented on the those platforms. Investigate other changes that may improve performance. Compare these results with other NXP and competitors products. Provide assistance to any customer activities that could result in design wins. Review the results with. Finally post the results and this guild so that groups within NXP may share them with customers.

Hardware Platform Identification

LS2080ARDB	Rev1.0	1867/533/1867	cortex A57

For board switch settings, please see to the corresponding reference manual.

Software Platform Identification

All software was built from QorIQ SDK ISO.

Boot Loader

U-boot 2016.01 with NXP-specific patches on top; Configuration for different platforms is as follows:

- EEMBC Netmark Application
- Source Code Download
- EEMBC Netmark version2 Source code can be downloaded from `www.eembc.org`
- Toolchain version: see Components section

Endianness

```
For PowerPC architecture:
Define correct Endianness by either modifying th_lite/<platform>/al/thcfg.h to

#if !defined( EE_BIG_ENDIAN ) && !defined( EE_LITTLE_ENDIAN)
#define EE_BIG_ENDIAN    (TRUE)
#define EE_LITTLE_ENDIAN (FALSE)
#endif

Or by modifying /util/make/gcc.mak to

COMPILER_DEFINES += -DEE_BIG_ENDIAN=1 -DEE_LITTLE_ENDIAN=0
```

```
For ARM architecture:
Define correct Endianness by either modifying th_lite/<platform>/al/thcfg.h to

#if !defined( EE_BIG_ENDIAN ) && !defined( EE_LITTLE_ENDIAN)
#define EE_BIG_ENDIAN    (FALSE)
#define EE_LITTLE_ENDIAN (TRUE)
#endif

Or by modifying /util/make/gcc.mak to

COMPILER_DEFINES += -DEE_BIG_ENDIAN=1 -DEE_LITTLE_ENDIAN=1
```

Data Types

```
th_lite/<platform>/al/eembc_dt.h has various data types definitions
If not already done, do:
#define HAVE_64    (1)

The default definition for data types is:
typedef unsigned long          e_u24;
typedef signed   long       e_s24;

typedef unsigned long         e_u32;
typedef signed   long       e_s32;

However, as ppc follows I32LP64, in case of 64 bit execution long will be considered 64 bit.
So the data type definitions should be changed to:

typedef unsigned int         e_u24;
typedef signed   int       e_s24;

typedef unsigned int        e_u32;
typedef signed   int       e_s32;
```

Build the benchmark with following compiler flags:

```
Cortex A7:

TOOLS = /opt/fsl-qoriq/2.0/sysroots/x86_64-fslsdk-linux/usr/bin/arm-fsl-linux-gnueabi/
CC = $(TOOLS)/arm-fsl-linux-gnueabi-gcc
AS = $(TOOLS)/arm-fsl-linux-gnueabi-as

```

Generate EEMBC binary for target board

1. Create a working directory.
2. Retrieve EEMBC v2.0 from www.eembc.org
3. Extract the EEMBC v2.0 source code
4. Edit the util/make/gcc.mak so that the CC variable points to the correct location of your compiler. See above table for detailed compiler flags and configuration
5. Build binary using the make command:

   ```
   make VER=v2 TOOLCHAIN=gcc THLITE=_lite all-lite
   ```

6. After the build is complete, copy binary files under `<EEMBC_2.0_INSTALL_DIR>/networking/gcc/bin_lite` to target board

12.1.3.2 Test Procedure

Test procedure for lmbench.

Running test and result collection

Deploy target board with corresponding software mentioned in previous section.

Put EEMBC Netmark binary compiled with optimized flags mentioned in section test environment on target board. EEMBC Netmark binary file list are as followings:

```
networking/tcpbulk_lite.exe
networking/tcpjumbo_lite.exe
networking/tcpmixed_lite.exe
networking/ip_pktcheckb1m_lite.exe
networking/ip_pktcheckb2m_lite.exe
networking/ip_pktcheckb4m_lite.exe
networking/ip_pktcheckb512k_lite.exe
networking/ip_reassembly_lite.exe
networking/ip_reassembly_lite.exe
networking/nat_lite.exe -INITTIME
networking/nat_lite.exe
networking/ospfv2_lite.exe
networking/qos_lite.exe
networking/routelookup_lite.exe
```

Run the benchmark

```
networking/tcpbulk_lite.exe -i 200000
networking/tcpjumbo_lite.exe -i 300000
networking/tcpmixed_lite.exe -i 100000
networking/ip_pktcheckb1m_lite.exe -i 50000
networking/ip_pktcheckb2m_lite.exe -i 30000
networking/ip_pktcheckb4m_lite.exe -i 10000
networking/ip_pktcheckb512k_lite.exe -i 100000
networking/ip_reassembly_lite.exe -INITTIME -i 5000
networking/ip_reassembly_lite.exe -i 5000
networking/nat_lite.exe -INITTIME -i 10000
networking/nat_lite.exe -i 10000
networking/ospfv2_lite.exe -i 10000
networking/qos_lite.exe -i 300
networking/routelookup_lite.exe -i 20000
```

The result will display as followings:

```
root@t4240qds:netv2_e6500_O2_bin# ./tcpbulk_lite -i 167000

>> BM: Networking: Route Lookup Benchmark V2.0R1
>> ID: NTW routelookup EEMBC
```

NOTE

For other platforms, use the ratio (CPU_Freq_target_platform/2000) to get the corresponding parameter. For example, if P4080DS's CPU freq is 1500MHz, then use 0.75 to multiply each parameter for above workloads.

There is a run to run variation in. So an average across 5 runs was taken for every result

Networking Version 2.0 Calculation

Networking Version 2.0 produces two aggregate "mark" scores: the TCPmark™ and the IPmark™

The IPmark is intended for developers of infrastructure equipment, while the TCPmark, which includes the TCP benchmark, focuses on client- and server-based network hardware.

The IPmark is the geometric mean of the scores for QoS, Route Lookup, OSPF, IP Reassembly, Network Address Translation, and the geometric mean of the individual scores for IP Packet check, all divided by 10:

```
IPmark = Geomean ((Geomean (IP Packet Check [0.5MB], IP Packet Check [1MB], IP Packet Check
[2MB], IP Packet Check [4MB]), QoS, Route Lookup, OSPF, IP Reassembly, NAT))/10
```

The TCPmark is the geometric mean of the scores for TCP Jumbo, TCP Bulk, and TCP Mixed divided by 100:

```
TCPmark = Geomean (TCP jumbo, TCP bulk, TCP Mixed)/100
```

To calculate a geometric mean, multiply all the results of the tests together and take the nth root of the product, where n equals the number of tests.

NAT and IP Reassembly Benchmarks

To calculate the iterations per second for the NAT and IP Reassembly benchmarks, it's necessary to run the benchmarks twice:

1. Run the benchmark with the flag -INITTIME supplied on the command line.
2. Run the benchmark without the flag -INITTIME supplied on the command line. The same executable must be run both times and the number of iterations must be identical.
3. Subtract the time of the first run from the time of the second run and calculate the iterations per second based on the calculated time.

The score reported for each device is a single-number figure of merit calculated by taking the geometric mean of the individual Networking scores and dividing by 395.184 . (This normalization factor is derived from the lowest score in this category on December 5, 2000.) Scores for each of the individual benchmarks within this suite allow designers to weight and aggregate the benchmarks to suit specific application requirements.

To calculate a geometric mean, multiply all the results (*) of the tests together and take the nth root of the product, where n equals the number of tests.

(*) Scores included in geometric mean:

```
•OSPF
•Route Lookup
•Packet Flow - 512 kbytes
•Packet Flow - 1 Mbyte
•Packet Flow - 2 Mbytes
```

NOTE

This calculation can also be found on EEMBC website:

```
http://eembc.org/benchmark/reports/mark.php?suite=NT2
```

12.1.4 LMBench

How to setup a board to baseline LMBench performance for QorIQ processor development boards.

12.1.4.1 Test Environment

Objectives

The first objective is to baseline the lmbench performance on QorIQ platform. Next identify any optimizations that have been discovered and ensure they are implemented on the those platforms. Investigate other changes that may improve performance. Compare these results with other NXP and competitors products. Provide assistance to any customer activities that could result in design wins. Review the results with. Finally post the results and this guild so that groups within NXP may share them with customers.

Hardware Platform Identification

Table 597. Target Platform

Board	Silicon Revision	Default Freqeuncy(Core/CCB/DDR)	Core Type

LS1043A	Rev1.0	1600/400/1600	cortex A53
LS2080A	Rev1.0	1867/533/1867	cortex A57

NOTE

For board switch settings, please see the corresponding reference manual.

Software Platform Identification

All software was built from QorIQ SDK ISO.

Boot Loader

U-boot 2016.01 with NXP-specific patches on top; Configuration for different platform like as following

For P2040/P2041/P3041, enable chip select interleaving and address hash, disabling ecc by hwconfig with syntax:

```
"hwconfig=fsl_ddr:bank_intlv=cs0_cs1,addr_hash=true,ecc=off"
```

For P4080/P5020/P5040, enable cacheline interleaving, chip select interleaving and address hash, disabling ecc by hwconfig with syntax:

```
 "hwconfig=fsl_ddr:ctlr_intlv=cacheline,bank_intlv=cs0_cs1,ecc=off,addr_hash=true"
```

For T4240/B4860/B4420/T1040/T2080, keep default configuration for DDR controller.

Lmbench Application

The roofs includes LMBench binaries which were built without optimization. For general latency performance, the default lmbench binary file in root file system will be ok. To get better bandwidth performance result, we need to modify compiler flags to enable "O3" optimization.

Followings are steps with assumption that SDK ISO had been installed and corresponding platform Yocto project is ready. Meanwhile, take p4080ds as one example in this document.

Get lmbench package with Yocto:

```
bitbake lmbench -c patch
```

Modify the Lmbench compiler flags in lmbench bitbake configuration file

```
find lmbench_3.0-a9.bb under directory {Yocto_install_dir}/{build_project}/meta-oe/meta-
oe/recipes-benchmark/lmbench
Append "-O3" in CC of line 24 in lmbench_3.0-a9.bb:

EXTRA_OEMAKE = 'CC="${CC} -O3" AR="${AR}" RANLIB="${RANLIB}" CFLAGS="${CFLAGS}" \
                LDFLAGS="${LDFLAGS}" LD="${LD}" OS="${TARGET_SYS}" \
```

```
For e6500-32bit:
Append "-m32 -O3 -fno-tree-vectorize " in CC of line 24 in lmbench_3.0-a9.bb:

EXTRA_OEMAKE = 'CC="${CC} -m32 -O3 -fno-tree-vectorize" AR="${AR}" RANLIB="${RANLIB}"
CFLAGS="${CFLAGS}" \
                LDFLAGS="${LDFLAGS}" LD="${LD}" OS="${TARGET_SYS}" \
For e6500-64bit:
Append "-m64 -O3 -fno-tree-vectorize " in CFLAGS of line 24 in lmbench_3.0-a9.bb:

EXTRA_OEMAKE = 'CC="${CC} -m64 -O3 -fno-tree-vectorize" AR="${AR}" RANLIB="${RANLIB}"
```

```
CFLAGS="${CFLAGS}" \
                LDFLAGS="${LDFLAGS}" LD="${LD}" OS="${TARGET_SYS}" \
```

Clean previous lmbench binary file without optimization flags.

```
rm -rf {Yocto_install_dir}/build_p4080ds_release/tmp/work/ppce500mc-fsl_networking-linux/
lmbench/3.0-a9-r2/lmbench-3.0-a9/bin/powerpc-fsl_networking-linux
```

Rebuild lmbench with optimization

```
bitbake -c compile -f lmbench
```

Get new lmbench binary files

1. For those only care bandwidth customer, they can pickup bandwidth benchark application from lmbench package directly under following folder:

   ```
   {Yocto_install_dir}/build_p4080ds_release/tmp/work/ppce500mc-fsl_networking-linux/
   lmbench/3.0-a9-r2/lmbench-3.0-a9/bin/powerpc-fsl_networking-linux/bw_mem
   ```

2. or they can deploy new lmbench binary files into rootfs

   ```
   bitbake fsl-image-core
   ```

12.1.4.2 Test Procedure

Test procedure for lmbench.

Running test and result collection

As described in section 2.2.2.1 and in Boot loader, separate u-boot image was burnt in alternate u-boot flash bank and the DUT is booted out of that bank.

Binaries compiled with different flags were run separately and then the data was collected for the binary showing the best results

There is a run to run variation in. So an average across 5 runs was taken for every result

Scripts for lmbench test.

Execution latency test script:

```
for i in `seq 1 5`
do
echo “Integer, integer64,float,double float execution latency”
lat_ops
done
```

Memory read latency test script:

```
for i in `seq 1 5`
do
echo “L1, L2, L3 and DDR read latency”
lat_mem_rd 100M
done
```

Memory bandwidth test script:

```
#!/bin/sh

for opt in rd wr rdwr cp frd fwr fcp bzero bcopy
do
   echo "L1 cache bandwidth $opt test with #$proc process"
   for idx in `seq 1 5`
   do
#8k is fit for all platform
       bw_mem -P 1 8k $opt
   done
       echo "L2 cache bandwidth $opt test"
#no L2 cache on P2040RDB, so it doesn’t need this.
# For different platform, L2 cache size is different. So it need to modify the data size.
```

```
# Here 40k is fit for P2041/ P3041/P4080/ /P5020/P5040
   for idx in `seq 1 5`
   do
       bw_mem -P 1 40k $opt
   done
       echo "L3 cache bandwidth $opt test"
# on dpaa platform, the minimum L3 cache size is 1M, so choose 750k for L3 cache test data
size
  for idx in `seq 1 5`
   do
       bw_mem -P 1 750k $opt
   done
       echo "Main mem bandwidth $opt test"
  for idx in `seq 1 5`
   do
       bw_mem -P 1 100m $opt
   done

done
```

12.2 Linux Networking and Storage

Linux Networking and Storage - Benchmark Reproducibility Guides

12.2.1 IPv4 Forward - DPAA

12.2.1.1 Linux DPAA IPv4

12.2.1.1.1 Test Environment

Benchmarking Objectives

The purpose of this guide is to show how to setup a Linux IPv4 Forwarding system on a NXP QorIQ DPAA platform and how to measure its performance.

NOTE

P4080DS was used for the demo. Please refer to the board's manual for other boards.

Linux Kernel	uImage-${PLATFORM}.bin
Device Tree	uImage-${PLATFORM}.dtb
File system	fsl-image-core-${PLATFORM}.ext2.gz.u-boot

NOTE

Target Development System Software

- **Boot loader**
  - U-boot 2016.01 with default ddr configurations:
  - For example, on P4080DS with two DDR controllers
    - Enable chip select interleaving mode: CS0+CS1
    - Enable DDR Controller interleaving mode: cache line (If there are two DDR controllers)
- **FMAN ucode**

  The SDK ISO contains the default ucode versions for all the supported platforms. Please refer to the “Linux Kernel and Device Drivers” section from the “Components” documentation chapter.
- **Operating system**

  Default kernel in ISO
- **Additional root filesystem considerations**

  The tests procedure for IPv4 forwarding makes use of the "arp" and "ifconfig" utilities. These are part of the net-tools package, which the root filesystem stored in the hard disk should have.

12.2.1.1.2 Test Procedure

This section describes the test procedure for various configurations of IPv4 forwarding

Test configuration

Different platforms have different Ethernet interfaces, please refer to SDK documentation (Selecting Ethernet interfaces) to configure Ethernet interfaces for Linux IPFWD.

At this point, we refer to P4080DS platform.

P4080DS have five 1Gb Ethernet interfaces(with 0x10 serdes protocol) and 2 10Gb Ethernet interfaces(with 0xe serdes protocol). fm1-gb1, fm2-gb0, fm2-gb1, fm2-gb2, fm2-gb3, fm1-10g, fm2-10g.

1. **4x1Gb Ethernet Ipv4 Forward 1024 flows(bi-directional) configuration:**
   - Spirent Testcenter configuration:
     - Port 1 to Port 2: Src: 192.168.1.2 – 192.168.1.17 -> Dst: 192.168.2.2 – 192.168.2.17
     - Port 2 to Port 1: Src: 192.168.2.2 – 192.168.2.17 -> Src: 192.168.1.2 – 192.168.1.17
     - Port 3 to Port 4: Src: 192.168.3.2 – 192.168.3.17 -> Dst: 192.168.4.2 – 192.168.4.17
     - Port 4 to Port 3: Src: 192.168.4.2 – 192.168.4.17 -> Src: 192.168.3.2 – 192.168.3.17

   - Linux configuration:

```
cat > do_arp.sh << EOF
#!/bin/sh

i=1
ifconfig fm2-gb0 192.168.1.1 netmask 255.255.255.0
ifconfig fm2-gb1 192.168.2.1 netmask 255.255.255.0
ifconfig fm2-gb2 192.168.3.1 netmask 255.255.255.0
ifconfig fm2-gb3 192.168.4.1 netmask 255.255.255.0
echo 1 > /proc/sys/net/ipv4/ip_forward

while expr \$i \< 17
do
ip=\`expr \$i + 1\`
hex=\`printf "%x" \$i\`
arp -s 192.168.1.\$ip 00:10:91:00:00:02
arp -s 192.168.2.\$ip 00:10:92:00:00:02
arp -s 192.168.3.\$ip 00:10:93:00:00:02
arp -s 192.168.4.\$ip 00:10:94:00:00:02
i=\`expr \$i + 1\`
```

```
done
EOF
#chmod +x do_arp.sh
#./do_arp.sh
#fmc -c config.xml -p policy_ipv4.xml -a
```

2. **2x10Gb Ethernet IPv4 Forward configuration:**

   1024 flows(bi-directional) between 2x10G Ethernet interfaces:

   - Spirent Testcenter configuration:
     - Port 1 -> Port 2 :
       - Src: 192.168.2.2 – 192.168.1.23
       - Dst: 192.168.3.2 – 192.168.2.24
     - Port 2 -> Port 1 :
       - Src: 192.168.3.2 – 192.168.1.24
       - Dst: 192.168.2.2 – 192.168.2.23

   - Linux configuration:

```
cat > do_arp.sh << EOF
#!/bin/sh

i=1
ifconfig fm1-10g 192.168.2.1 netmask 255.255.255.0
ifconfig fm2-10g 192.168.3.1 netmask 255.255.255.0
echo 1 > /proc/sys/net/ipv4/ip_forward

while expr \$i \< 23
do
ip=\`expr \$i + 1\`
hex=\`printf "%x" \$i\`
arp -s 192.168.3.\$ip 00:10:94:00:00:01
arp -s 192.168.2.\$ip 00:10:95:00:00:01
i=\`expr \$i + 1\`
done
arp -s 192.168.3.24 00:10:94:00:00:01
EOF
#chmod +x ./do_arp.sh
#./do_arp.sh
#fmc -c config.xml -p policy_ipv4.xml -a
```

Running the test

After Spirent Testcenter application is completely configured, the IPv4 automated forward throughput measurement can be started.

Appendix

In order to get better Linux IPFWD performance on P2040RDB/P3041DS/P4080DS/P5020DS/P5040DS which are FManv1, the PCD configuration must be applied before starting the Linux IPFWD performance test (by running the fmc tool as seen in the commented lines above).

Here is one example for P4080DS:

FMC configuration files for optimization of Linux IPv4 forward can be found in /etc/fmc/config in rootfs. In this directory, there are specific configuration and policy files for each supported RCW. Using the RCW, numerous platform parameters can be configured, including the SERDES protocols used by the P4080DS board. For the 4G traffic mode, the config.xml should have the 4 ports configuration entries:

```
<cfgdata>
   <config>
      <engine name="fm1">
         <port type="MAC" number="1" policy="fm_policy_9"/>
         <port type="MAC" number="2" policy="fm_policy_10"/>
         <port type="MAC" number="3" policy="fm_policy_11"/>
         <port type="MAC" number="4" policy="fm_policy_12"/>
      </engine>
   </config>
</cfgdata>
```

For the 20G traffic mode, change config.xml to have the 2x10G ports configuration entries:

```
<cfgdata>
   <config>
      <engine name="fm0">
         <port type="MAC" number="9" policy="fm_policy_7"/>
      </engine>
      <engine name="fm1">
         <port type="MAC" number="9" policy="fm_policy_15"/>
      </engine>
   </config>
</cfgdata>
```

For the other platforms, use the existing xml files from /etc/fmc/config.

12.2.1.2 IPv4 Forward - T1024RDB

12.2.1.2.1 Test Environment

The first objective is to baseline the Linux IPv4 Forward performance. Next identify any optimizations that have been discovered and ensure they are implemented on the QorIQ DPAA platform. Investigate other changes that may improve performance. This guide is intended to provide details for reproducing Linux IPv4 packet forwarding performance results for T1024RDB.

Platform Configurations

Platform	Platform Rev.	Silicon Rev.	Default frequency Core/CCB/DDR/FMan	SerDes Protocol	Config. Name
T1024RDB	Rev C	Rev 1.0	• CPU - 1400 MHz • CCB - 400 MHz • DDR - 1600 MHz • FMan - 700 MHz	• 0x95 • 0x135	• RRX_PPP_95 • RNS_NPP_135

Network Simulator

Spirent TestCenter Performance Analysis System

- Spirent Testcenter version: 4.41
- Choose Bound Stream Block for Traffic generator
- Choose Wizard -> Benchmarking -> RFC2544 -> Throughput Test -> Sequencer sequencer for throughput test
- Testcenter configuration:
  - Test Duration: 60 Seconds
  - Resolution: 0.1%
  - Packet Loss Rate: 0.001 %
  - Packet Size: 84(ipv6:86), 408,1424(ipv6-aes:1424) bytes

Software Platform Identification

All software was built from SDK ISO. Please refer to following images:

Table 599. Images

Target Development System Software	Image file name/Description
FMan ucode	T1024 rev 1.0 - fsl_fman_ucode_t1024_r1.0_106_4_17.bin(Please refer to SDK document to use correct ucode version)
RCW	T1024RDB: RNS_NPP_135/rcw_135_1400MHz.rcw T1024RDB: RRX_PPP_95/rcw_95_1400MHz.rcw
Boot loader	u-boot-T1024RDB.bin
Linux Kernel	uImage-t1024rdb.bin
Device Tree	uImage-t1024rdb.dtb
Default File system	fsl-image-core-t1024rdb.ext2.gz.u-boot

- **Target Development System Software**
  - **Boot loader**
    - U-boot 2015.01 with default ddr configurations:
    - T1024RDB with one DDR controllers
      - Enable chip select interleaving mode: CS0+CS1
  - **FMAN ucode**

    fsl_fman_ucode_t1024_r1.0_106_4_17.bin.
  - **Operating system**

    Default kernel in ISO
  - **Additional root filesystem considerations**
    - For Linux: uImage-t1024rdb.bin and fsl-image-core-t1024rdb.ext2.gz.u-boot

12.2.1.2.2 Test Procedure

This section describes the test procedure for various configurations of IPv4 forwarding

Test configuration

Different platforms have different Ethernet interfaces, please refer to SDK documentation (Selecting Ethernet interfaces) to configure Ethernet interfaces for Linux IPV4 forward.

T1024RDB have two RCW:

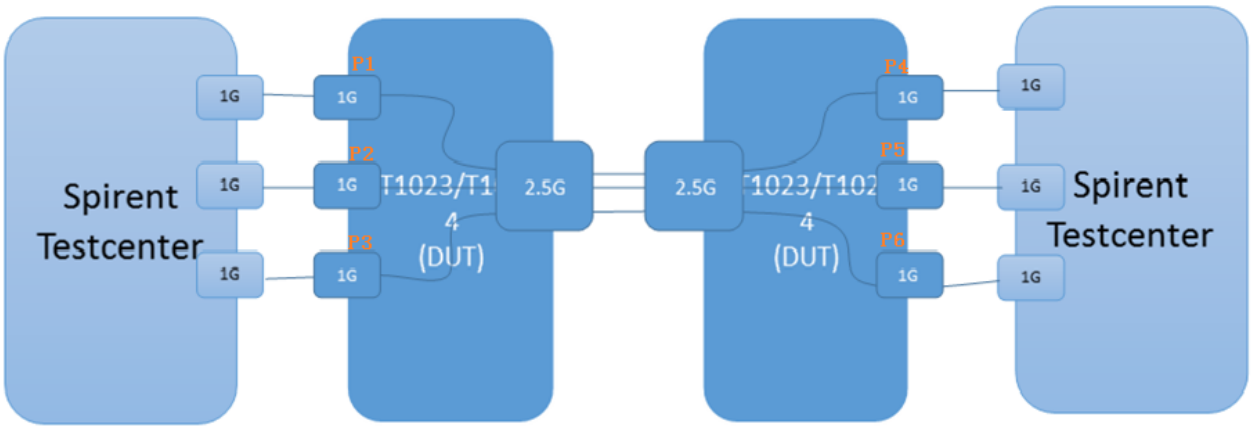
- RCW_135: 1 x 1Gb rgmii ports + 1 x 2.5G SGMII port + 2 x mini_PCIE ports
- RCW_95: 2 x 1Gb rgmii port + 1 x 10G XFI port + 1 x PCIE port + 2 x mini_PCIE ports

The 10G XFI port could speed down to 2.5G. So traffic which will go through DPAA on T1024RDB will use following Ethernet interfaces:

- RCW_135: fm1-mac3(2.5G)/fm1-mac4(RGMII)/eth*(mini_PCIE)/eth*(mini_PCIE)
- RCW_95: fm1-mac1(2.5G)/fm1-mac4(RGMII)/fm1-mac3(RGMII)/eth*(mini_PCIE)

show traffic flow which will go through to DPAA:

-



Note:

- Please use one TC to send traffic, placing two TC in the picture is aimed at showing ports' connection more clear.
- Ports Property:
  - For RCW_135:Port1 and Port4 are RGMII ports.others ports are all mini_PCIE;
  - For RCW_95:Port1/Port2/Port3/Port4 are RGMII ports.others ports are mini_PCIE;

1. 4.1.1 IPv4 Forward 6g flows(bi-directional) configuration:
   - Spirent Testcenter configuration for Linux IPv4 Forward:
     - Port 1 to Port 4 :
       - Src: 192.85.1.2 – 192.85.1.17 -> Dst: 192.85.4.2 –192.85.4.17
       - SMac: 00:10:94:00:00:01 -> DMac: <fm1-mac3(left) mac address>
       - Gateway: 192.85.1.1
     - Port 2 to Port 5 :
       - Src: 192.85.2.2 – 192.85.2.17 -> Dst: 192.85.5.2 – 192.85.5.9
       - SMac: 00:10:94:00:00:02 -> DMac: <fm1-mac3(left) mac address>
       - Gateway: 192.85.2.1
     - Port 3 to Port 6:

- Src: 192.85.3.2 – 192.85.3.9 -> Dst: 192.85.6.2 – 192.85.6.17
- SMac: 00:10:94:00:00:03 -> DMac: <fm1-mac3(left) mac address>
- Gateway: 192.85.3.1

- Port 4 to Port 1:
  - Src: 192.85.4.2 – 192.85.4.17 -> Dst: 192.85.1.2 – 192.85.1.17
  - SMac: 00:10:94:00:00:05 -> DMac: <fm1-mac3(right) mac address>
  - Gateway: 192.85.4.1
- Port 5 to Port 2 :
  - Src: 192.85.5.2 – 192.85.5.9 -> Dst: 192.85.2.2 – 192.85.2.17
  - SMac: 00:10:94:00:00:04 -> DMac: <fm1-mac3(right) mac address>
  - Gateway: 192.85.5.1
- Port 6 to Port 3:
  - Src: 192.85.6.2 – 192.85.6.17 -> Dst: 192.85.3.2 – 192.85.3.8
  - SMac: 00:10:94:00:10:01 -> DMac: <fm1-mac3(right) mac address>
  - Gateway: 192.85.6.1

Running the test

After Spirent Testcenter application is completely configured, the IPv4 automated forward throughput measurement can be started.

Appendix

1. No need to configure PCD when test Linux IPFwd performance.
2. For RCW_135, as there are only 3 1G ports, we need use all of them to send traffic, suggests boot from lan server to run fully-automatic test.
3. Limited by board design, there is only one 1G fman port when 2.5G SGMII works, we only use one fman port to test usdpaa and asf on T1024RDB:2.5G SGMII port.
4. Limited by board design, there is only one 1G fman port when 2.5G SGMII works, for linux IPFwd and IPSec test, we can use 10G PCIe card to test performance of the 2.5G SGMII port.

12.2.1.3 IPv4 Forward - T1040D4RDB

12.2.1.3.1 Test Environment

The first objective is to baseline the Linux IPv4 Forward performance. Next identify any optimizations that have been discovered and ensure they are implemented on the QorIQ DPAA platform. Investigate other changes that may improve performance. This guide is intended to provide details for reproducing Linux IPv4 packet forwarding performance results for T1040D4RDB.

Platform Configurations

Platform	Platform Rev.	Silicon Rev.	Default frequency Core/CCB/DDR/FMan	SerDes Protocol	Config. Name
T1040D4RDB	Rev A	Rev 1.1	• CPU - 1400 MHz • CCB - 600 MHz • DDR - 1600 MHz • FMan - 600 MHz	0x66	RR_P_66

Network Simulator

Spirent TestCenter Performance Analysis System

  - For Linux: uImage-t1040d4rdb.bin and fsl-image-core-t1040d4rdb.ext2.gz.u-boot
  - For ASF: uImage.ppce5500-asf and fsl-image-asf-t1040d4rdb.ext2.gz.u-boot

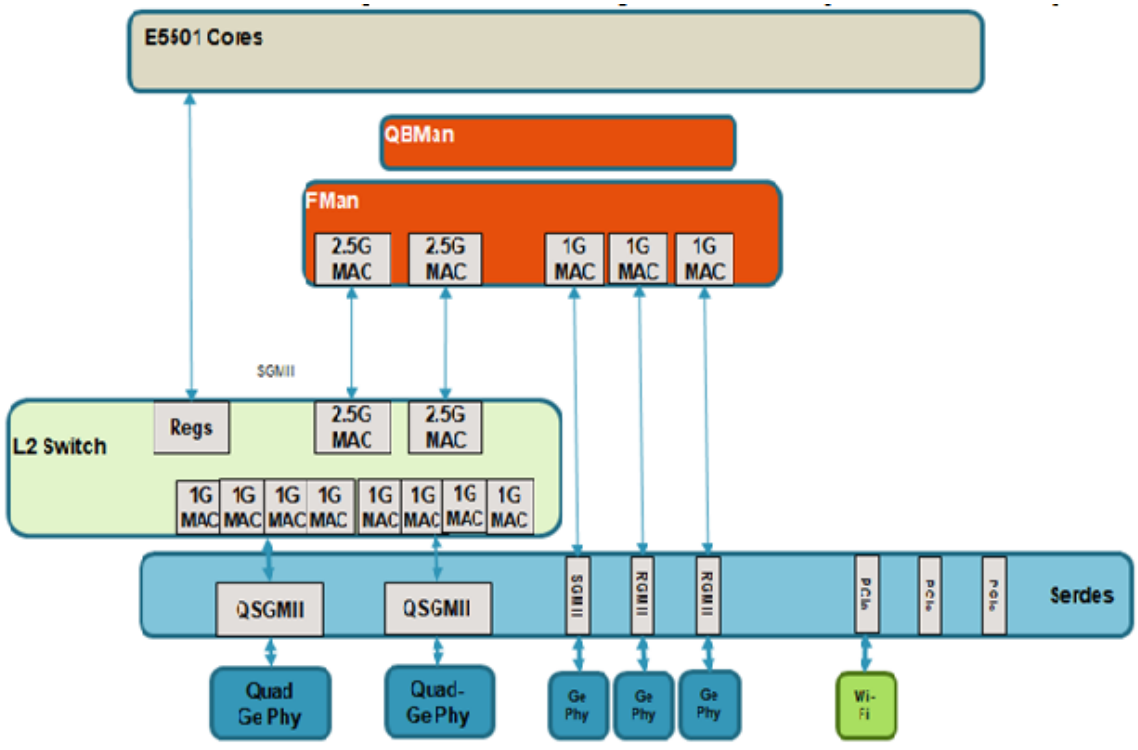
12.2.1.3.2 Test Procedure

This section describes the test procedure for various configurations of IPv4 forwarding

Test configuration

Different platform has different Ethernet interface, please refer to SDK document (Selecting Ethernet interfaces) to configure Ethernet interfaces for 8x1G Linux IPFWD.

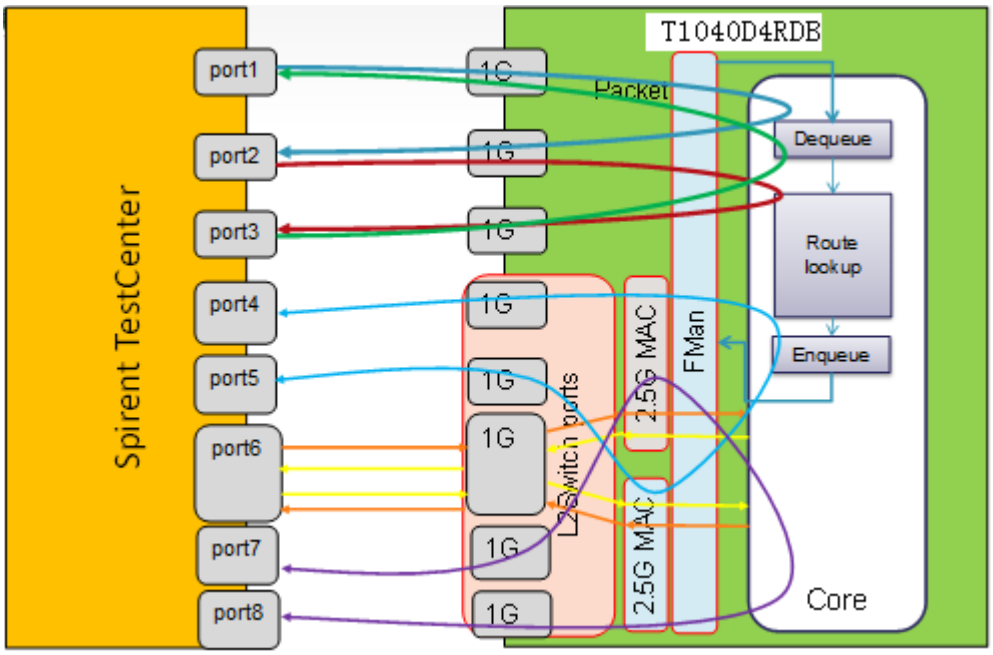
T1040D4RDB have 8 1Gb L2 switch ports which are external ports and 1 SGMII and 2 RGMII ports, like as followings:



Note: two internal 2.5G mac of l2switch which connected to Fman's two 2.5G mac.

So traffic which will go through DPAA on T1040D4RDB will use following Ethernet interfaces: fm1-gb0(2.5G)/fm1-gb1(2.5G)/ fm1-gb2(SGMII)/fm1-gb3(RGMII)/fm1-gb4(RGMII). And the maximum traffic what we can inject to DPAA is 8Gbps. Thus,

Linux/ASF/USDPAA IPv4 forward chooses five L2 switch ports and three SGMII/RGMII ports for benchmark test. The following diagram show traffic flow which will go through to DPAA:



1. **4.1.1 I8x1Gb Ethernet IPv4 Forward 1020 flows(bi-directional) configuration:**
   - Note: DMAC is mac address of fm1-gbx (0, 1, 2, 3, 4) of T1040RDB board. Please make change based on target board.
   - Spirent Testcenter configuration for Linux IPv4 Forward:
     - Port 1 to Port 5 < 1Gbps >:
       - Src: 192.85.1.2 – 192.85.1.18 -> Dst: 192.85.4.2 –192.85.4.5

```

Running the test

After Spirent Testcenter application is completely configured, the IPv4 automated forward throughput measurement can be started.

Appendix

1. **No need to configure PCD**

12.2.2 IPv4 Forward - eTSEC

12.2.2.1 Test Environment

Benchmarking Objectives

The purpose of this guide is to show how to setup a IPv4 Forwarding system on a NXP QorIQ processor based system and how to measure its performance.

NOTE

LS1021ATWR was used for the demo. Please refer to the board's manual for other boards.

After a baseline of performance and identifying optimizations these activities are possible:

1. Review the results with SDK development and any other groups or individuals who may have valuable input that could increase performance.
2. Post the results and this guide so that groups within NXP may share them with customers.
3. Compare these results with other NXP and competitors' products.
4. Provide assistance to any customer activities that could result in design wins.

Once established, the baseline can be used as a starting point for investigating other changes that may improve performance.

Test environment for eTSEC Platforms

A list of eTSEC platforms:

1. LS1021ATWR

For board switch settings, please see to the corresponding reference manual. Operating frequencies (CPU, CCB, DDR) must be set to the highest allowed values (check the product reference manual).

Test Equipment

The test equipment for this effort:

- Network Traffic generator and analyzer:
  1. SmartBits SMB-600B 2 slot chassis.
  2. 2 x LAN-3321A TeraMetric modules.
- SmartFlow application

Software Platform Identification

All software was built from SDK ISO.

Table 601. Target Development System Software

Resource	Description
Boot Loader	U-boot with NXP-specific patches was included SDK ISO. Configuration: • Enable cacheline interleaving mode: CS0+CS1 (if the DIMM support chip select interleaving) • Enable DDR controller interleaving mode: cache line (if there are two DDR controllers)
Operating system	Linux Source code with NXP-specific patches was included SDK ISO. This is the default kernel package for the SDK configuration.
Root filesystem considerations	The testing procedure makes use of the utilities **arp**, **ifconfig** and **ethtool**. These are part of the net-tools and iproute2 packages, which should be included in the root filesystem.

12.2.2.2 Test Procedure

Test procedure for IPv4 Forwarding benchmarking tests.

Test configuration

The configuration used is detailed in the figure below:

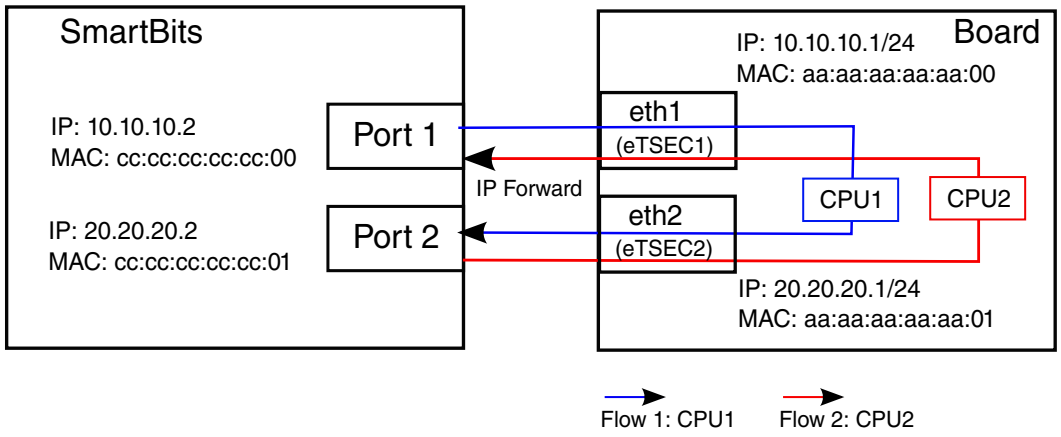

Figure 379. Configurations

Test Equipment Configuration

Test parameters:

Table 602. Test equipment parameters

Parameter	Description
Frame Size:	• 64 bytes • 128 bytes • 256 bytes • 390 bytes • 512 bytes • 1024 bytes • 1280 bytes • 1518 bytes
Test Duration	• 60 seconds
Resolution	• 0.1%
Acceptable Frame Loss	• 0.001%

Test Setup

Table 603. Target Development System Software

Task	Description

Make sure that operating frequencies (CPU, CCB, DDR) are set to the highest allowed values (check the corresponding platform reference manual);	• `CPU:  Freescale LayerScape LS1021E, Version: 2.0, (0x87081120)`
	`Clock Configuration:`
	`CPU0(ARMV7):1000 MHz,`
	`Bus:300 MHz, DDR:800 MHz (1600 MT/s data rate),`

Kernel configuration: The provided Linux kernel comes with a default configuration file). In order to obtain better performance, the optimizations shown at left must be enabled:	• `CONFIG_DEBUG_KERNEL` - disabled (default: built-in). • `CONFIG_NR_CPUS` - 2 (default: 8). • `CONFIG_USB_SUPPORT` - disabled (default: built-in).
Kernel boot parameters used:	• `root=/dev/ram rw console=ttyS0,115200 ramdisk_size=1000000 log_buf_len=128K` **NOTE** ramboot is preferred when performing benchmarking, since nfsboot might incur performance hit due to inherent network traffic

Table continues on the next page...

Table 603. Target Development System Software (continued)

Task	Description

Set up SMP interrupt affinities in order to route the flows to separate CPUs. For example:	• Make Flow1 affine to CPU1, that is, setup affinity of eth1_g0_rx and eth2_g0_tx interrupt handlers to 1, for example:
	• `#echo 1 > /proc/irq/36/smp_affinity`
	`#echo 1 > /proc/irq/31/smp_affinity`
	• Respectively make Flow2 affine to CPU2, meaning eth2_g0_rx and eth1_g0_tx have their affinity set to 2, for instance:
	• `#echo 2 > /proc/irq/32/smp_affinity`
	`#echo 2 > /proc/irq/35/smp_affinity`

Tune `Gianfar` driver parameters:	• Setting the Rx/Tx interrupt coalescing thresholds for packet count and microseconds:
	• `#ethtool -C eth1 rx-frames 32 rx-usecs 22`
	`#ethtool -C eth1 tx-frames 32 tx-usecs 22`
	`#ethtool -C eth2 rx-frames 32 rx-usecs 22`
	`#ethtool -C eth2 tx-frames 32 tx-usecs 22`
	• where ~11 usecs is the approx. time needed to transfer 16 frames of 64B payload each at line rate over a 1Gbit link

Setup the arp entries and enable IPv4 forwarding (see figure above):	• `#arp -s 10.10.10.2 cc:cc:cc:cc:cc:00 -i eth1`
	`#arp -s 20.20.20.2 cc:cc:cc:cc:cc:01 -i eth2`
	`#sysctl -w net.ipv4.ip_forward=1`

To further optimize the throughput, kill unneeded user space processes (if any). For example:	• `/etc/init.d/lighttpd stop`
	`/etc/init.d/crond stop`
	`/etc/init.d/sshd stop`
	`/etc/init.d/xinetd stop`
	`/etc/init.d/cups stop`
	`/etc/init.d/nfsserver stop`
	NOTE
	The exact commands depend on the features included in the root filesystem.

Results

The SmartFlow application reports the throughput results at the end of the test session.

12.2.3 IPSec Forward - DPAA

12.2.3.1 IPSec Forward - DPAA

12.2.3.1.1 Test Environment

Baseline the Linux IPSec performance

Objective

Identify any optimizations that have been discovered and ensure they are implemented on the QorIQ DPAA platform. Investigate other changes that may improve performance. This guide provides details for reproducing Linux IPSec forwarding performance results.

Network Simulator

Spirent TestCenter Performance Analysis System

- Spirent Testcenter version: 4.41
- Choose Bound Stream Block for Traffic generator
- Choose Wizard -> Benchmarking -> RFC2544 from Spirent Testcenter to create command sequencer for throughput test
- Manual ZLT method:
  - Test Duration: 60 Seconds
  - Resolution: 0.1%
  - Packet Loss Rate: 0.001 %
  - Packet Size: 84(ipv6:86), 408,1424(ipv6-aes:1424) bytes

Target Development System Software

Software Platform Identification

All software was built from the QorIQ SDK ISO.

Boot loader

U-boot:

- Enable Cacheline interleaving mode: CS0+CS1
- Enable DDR Controller interleaving mode: cache line (If there are two DDR controllers),

Operating System

Default kernel in ISO

NOTE: For **T2080QDS** and **T2080RDB** performance measurements, the following kernel parameters must be used:

- CONFIG_FSL_DPAA_ETH_MAX_BUF_COUNT=512
- CONFIG_FSL_DPAA_ETH_REFILL_THRESHOLD=384

Additional root filesystem considerations

The tests procedure for IPv4 forwarding makes use of the "arp", "ifconfig" and “ip” utilities. These are part of the net-tools and iproute2 packages, which the root filesystem stored in the hard disk should have.

12.2.3.1.2 Test Procedure

Test procedure for various configurations of IPv4 Sec & Forwarding. Let’s refer to P3041DS board for example.

Test Configuration

P3041 has five 1Gb Ethernet interfaces and 1 10Gb Ethernet interface. There are fm1-gb0, fm1-gb1, fm1-gb2, fm1-gb3, fm1-gb4, fm1-10g.

Linux Ipv4 SEC Forward Configuration

- 128 tunnels (bi-directional) configuration:
  - Spirent TestCenter configuration:
    - Port 1 to Port 2: Src: 192.85.1.2 – 192.85.1.9 -> Dst: 192.86.1.2 – 192.86.1.9
    - Port 2 to Port 1: Src: 192.86.1.2 – 192.86.1.9 -> Src: 192.85.1.2 – 192.85.1.9

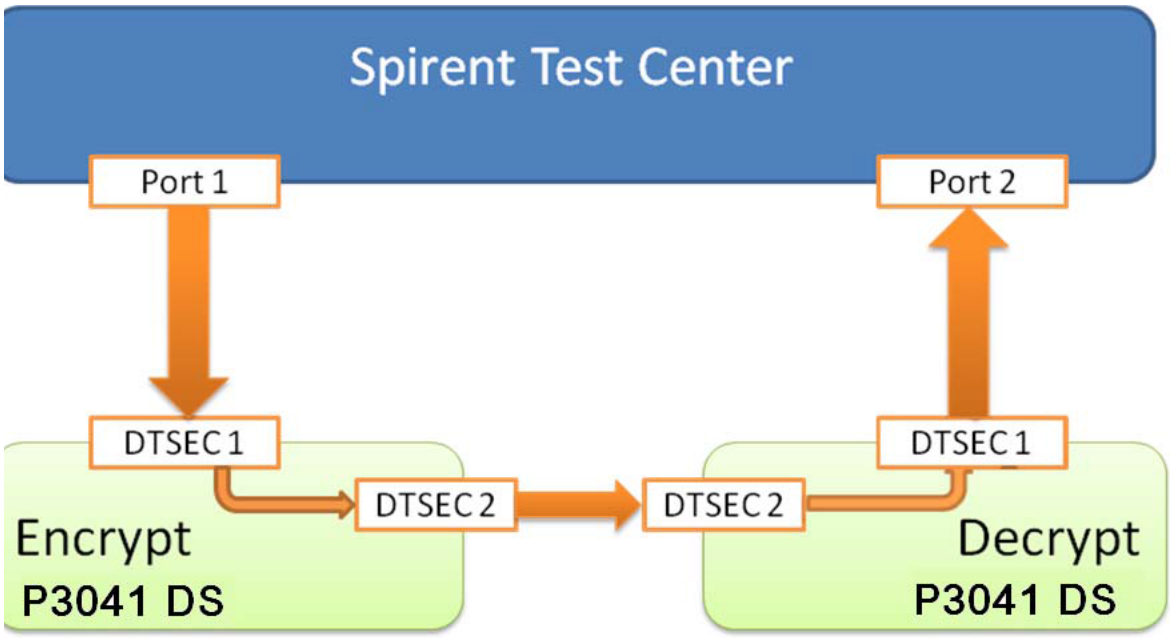

Figure 380. IPSecfwd Configuration

- Linux configuration:
  - The Linux configuration file is listed below.
  - On left gateway(Encrypt) board, run: bash iproute_128tunnels_p3041.sh left
  - On right gateway(Decrypt) board run: iproute_128tunnels_p3041.sh right

NOTE

The default left gateway board is board_left, and the right is board_right, you can modify the script "iproute_128tunnels_p3041.sh" what you want.

NOTE

For 2x10G linux ipsec, only need to replace above 1G interface to 10G interface.

Running the Test

After Sprient Testcenter application has been completely configured, start to send traffic for measuring IPv4 IPsec throughput.

Linux Configuration File

```
#!/bin/bash
eth0=fm1-gb0
eth1=fm1-gb1

make_esp_tunnel() {

# ESP SAs do$dir2g encryption us$dir2g 192 bit long keys (168 + 24 parity)

        ifconfig $eth1 up
        route add default dev $eth1

            ;;
esac
```

FMC configuration

In order to achieve the greatest performance, one needs to ensure that PCD files are applied. In order to do that, after applying the tunnel configuration above, one needs to execute a command similar to the following on both the *left* as well as the *right* board:

```
root@left :~# fmc -c /etc/fmc/config/private/<board>/<RCW name>/config.xml -p /etc/fmc/
config/private/<board>/<RCW name>/policy_ipv4.xml -a
```

Replace in the command above the board with the full name of the board i.e. T2080QDS and the RCW name with the name of the RCW file used on the board. For instance, for a T2080QDS, which is configured to use RR_PNNPPH_66_15, the command above would translate as below:

```
root@left :~# fmc -c /etc/fmc/config/private/t2080qds/RR_PNNPPH_66_15/config.xml -
p /etc/fmc/config/private/t2080qds/RR_PNNPPH_66_15/policy_ipv4.xml -a
```

For more information regarding the way the DPAA1 Ethernet driver and the FMC configuration file(s) interact, please consult the following topic: "FMC, FMD, and the ethernet Driver"

12.2.3.2 IPSec Forward - T1024RDB

12.2.3.2.1 Test Environment

The first objective is to baseline the Linux IPv4 Forward performance. Next identify any optimizations that have been discovered and ensure they are implemented on the QorIQ DPAA platform. Investigate other changes that may improve performance. This guide is intended to provide details for reproducing Linux IPv4 packet forwarding performance results for T1024RDB.

Platform Configurations

Platform	Platform Rev.	Silicon Rev.	Default frequency Core/CCB/DDR/FMan	SerDes Protocol	Config. Name
T1024RDB	Rev C	Rev 1.0	• CPU - 1400 MHz • CCB - 400 MHz • DDR - 1600 MHz • FMan - 700 MHz	• 0x95 • 0x135	• RRX_PPP_95 • RNS_NPP_135

Network Simulator

Spirent TestCenter Performance Analysis System

- Spirent Testcenter version: 4.41
- Choose Bound Stream Block for Traffic generator
- Choose Wizard -> Benchmarking -> RFC2544 -> Throughput Test -> Sequencer sequencer for throughput test
- Testcenter configuration:
  - Test Duration: 60 Seconds
  - Resolution: 0.1%
  - Packet Loss Rate: 0.001 %
  - Packet Size: 84(ipv6:86), 408,1424(ipv6-aes:1424) bytes

Software Platform Identification

All software was built from SDK ISO. Please refer to following images:

Table 604. Images

Target Development System Software	Image file name/Description
FMan ucode	T1024 rev 1.0 - fsl_fman_ucode_t1024_r1.0_106_4_17.bin(Please refer to SDK document to use correct ucode version)
RCW	T1024RDB: RNS_NPP_135/rcw_135_1400MHz.rcw T1024RDB: RRX_PPP_95/rcw_95_1400MHz.rcw
Boot loader	u-boot-T1024RDB.bin
Linux Kernel	uImage-t1024rdb.bin
Device Tree	uImage-t1024rdb.dtb
Default File system	fsl-image-core-t1024rdb.ext2.gz.u-boot

- **Target Development System Software**
  - **Boot loader**
    - U-boot 2015.01 with default ddr configurations:
    - T1024RDB with one DDR controllers
      - Enable chip select interleaving mode: CS0+CS1
  - **FMAN ucode**

    fsl_fman_ucode_t1024_r1.0_106_4_17.bin.
  - **Operating system**

    Default kernel in ISO
  - **Additional root filesystem considerations**
    - For Linux: uImage-t1024rdb.bin and fsl-image-core-t1024rdb.ext2.gz.u-boot

12.2.3.2.2 Test Procedure

This section describes the test procedure for various configurations of IPv4 IPSec forwarding

Test configuration

Different platforms have different Ethernet interfaces, please refer to SDK documentation (Selecting Ethernet interfaces) to configure Ethernet interfaces for Linux IPSec forward.

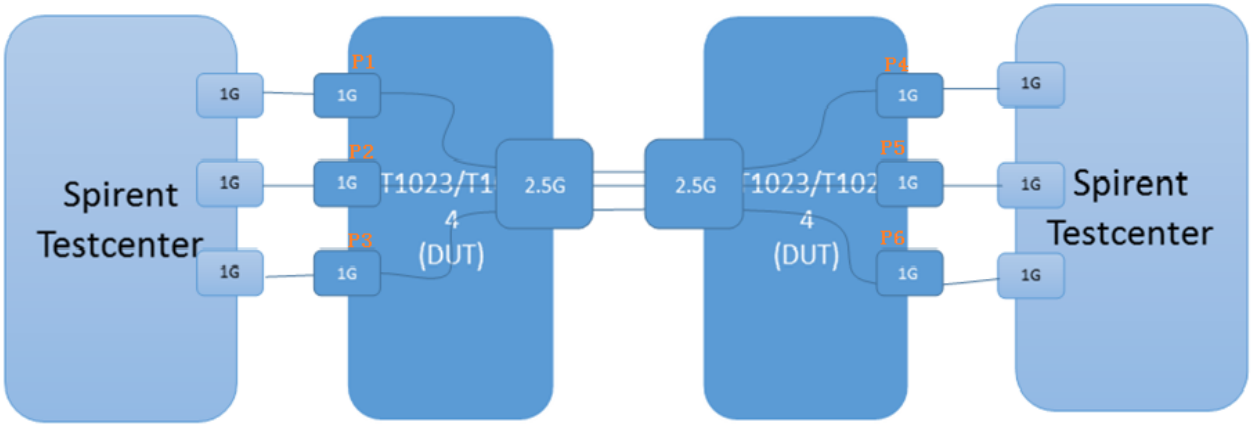
T1024RDB have two RCW:

- RCW_135: 1 x 1Gb rgmii ports + 1 x 2.5G SGMII port + 2 x mini_PCIE ports
- RCW_95: 2 x 1Gb rgmii port + 1 x 10G XFI port + 1 x PCIE port + + 2 x mini_PCIE ports

The 10G XFI port could speed down to 2.5G. So traffic which will go through DPAA on T1024RDB will use following Ethernet interfaces:

- RCW_135: fm1-mac3(2.5G)/fm1-mac4(RGMII)/eth*(mini_PCIE)/eth*(mini_PCIE)
- RCW_95: fm1-mac1(2.5G)/fm1-mac4(RGMII)/fm1-mac3(RGMII)/eth*(mini_PCIE)

show traffic flow which will go through to DPAA:



Note:

- Please use one TC to send traffic, placing two TC in the picture is aimed at showing ports' connection more clear.
- Ports Property:
  - For RCW_135:Port1 and Port4 are RGMII ports.others ports are all mini_PCIE;
  - For RCW_95:Port1/Port2/Port3/Port4 are RGMII ports.others ports are mini_PCIE;

1. 4.1.1 IPv4 SEC Forward 6g 128 flows(bi-directional) configuration:(take RCW_135 as an example)
   - Spirent Testcenter configuration for Linux IPv4 SEC Forward:
     - Port 1 to Port 4 :
       - Src: 192.85.1.2 – 192.85.1.9 -> Dst: 192.86.1.2 –192.85.4.5
       - SMac: 00:10:94:00:00:01 -> DMac: <fm1-mac3(left) mac address>
       - Gateway: 192.85.1.1
     - Port 2 to Port 5 :
       - Src: 192.87.1.2 – 192.87.1.5 -> Dst: 192.88.1.2 – 192.85.1.5
       - SMac: 00:10:94:00:00:03 -> DMac: <fm1-mac3(left) mac address>
       - Gateway: 192.87.1.1
     - Port 3 to Port 6:
       - Src: 192.89.1.2 – 192.89.1.5 -> Dst: 192.90.1.2 – 192.90.1.5
       - SMac: 00:10:94:00:00:05 -> DMac: <fm1-mac3(left) mac address>
       - Gateway: 192.89.1.1
     - Port 4 to Port 1:
       - Src: 192.86.1.2 – 192.86.1.5 -> Dst: 192.85.1.2 – 192.85.1.9
       - SMac: 00:10:94:00:00:02 -> DMac: <fm1-mac3(right) mac address>
       - Gateway: 192.86.1.1
     - Port 5 to Port 2 :
       - Src: 192.88.1.2 – 192.88.1.5 -> Dst: 192.87.1.2 – 192.87.1.5
       - SMac: 00:10:94:00:00:04 -> DMac: <fm1-mac3(right) mac address>
       - Gateway: 192.88.1.1
     - Port 6 to Port 3:

- Src: 192.90.1.2 – 192.90.1.5 -> Dst: 192.89.1.2 – 192.89.1.5
- SMac: 00:10:94:00:00:06 -> DMac: <fm1-mac3(right) mac address>
- Gateway: 192.90.1.1

- tunnel ip for Linux IPv4 SEC Forward:
  - tunnel ip of 2.5G SGMII port on left board :200.200.100.10
  - tunnel ip of 2.5G SGMII port on right board :200.200.100.20

Running the test

After Spirent Testcenter application is completely configured, the IPv4 SEC automated forward throughput measurement can be started.

Appendix

1. No need to configure PCD when test Linux IPFwd performance.
2. For RCW_135, as there are only 3 1G ports, we need use all of them to send traffic, suggests boot from lan server to run fully-automatic test.
3. Limited by board design, there is only one 1G fman port when 2.5G SGMII works, we only use one fman port to test usdpaa and asf on T1024RDB:2.5G SGMII port.
4. Limited by board design, there is only one 1G fman port when 2.5G SGMII works, for linux IPFwd and IPSec test, we can use 10G PCIe card to test performance of the 2.5G SGMII port.

12.2.3.3 IPSec Forward - T1040D4RDB

12.2.3.3.1 Test Environment

Benchmarking Objectives

The purpose of this guide is to show how to setup an IPSec Forwarding system on a NXP QorIQ processor based system and how to measure its performance.

Platform Configurations: T1040D4RDB

- Board: t1040D4RDB, board rev: 0x01, CPLD ver: 0x06, vBank: 4
- CPU0: t1040E, Version: 1.0
- Core: e5500, Version: 2.0
- Clock Configuration:
  - CPU0:1400 MHz, CPU1:1400 MHz, CPU2:1400 MHz, CPU3:1400 MHz,
  - CCB:600 MHz,
  - DDR:800 MHz (1600 MT/s data rate) (Asynchronous), IFC:150 MHz
  - QE: 300MHz
  - FMAN1: 600 MHz
  - QMAN: 300MHz
  - PME: 300 MHz
- 1 on board SGMII port and 2 on board RGMII ports
- 8 Gigabit switch ports are external ports and are connected to external Phys

Network Simulator: Spirent TestCenter Performance Analysis System

- Spirent Testcenter version: 4.41
- Choose Bound Stream Block for Traffic generator

- Choose Wizard -> Benchmarking-> RFC2544-> Throughput Test-> Sequencer
- Testcenter configuration:
  - Test Duration: 60 Seconds
  - Resolution: 0.1%
  - Packet Loss Rate: 0.001 %
  - Packet Size: 84(ipv6:86), 408,1424(ipv6-aes:1424) bytes

Software Platform Identification

All software was built from SDK ISO.

Host development System Software Target Development System Software **Boot loader**

- U-boot 2015. 01 with default ddr configurations:
- T1040D4RDB with one DDR controllers
  - Enable chip select interleaving mode: CS0+CS1

uImage and Root filesystem

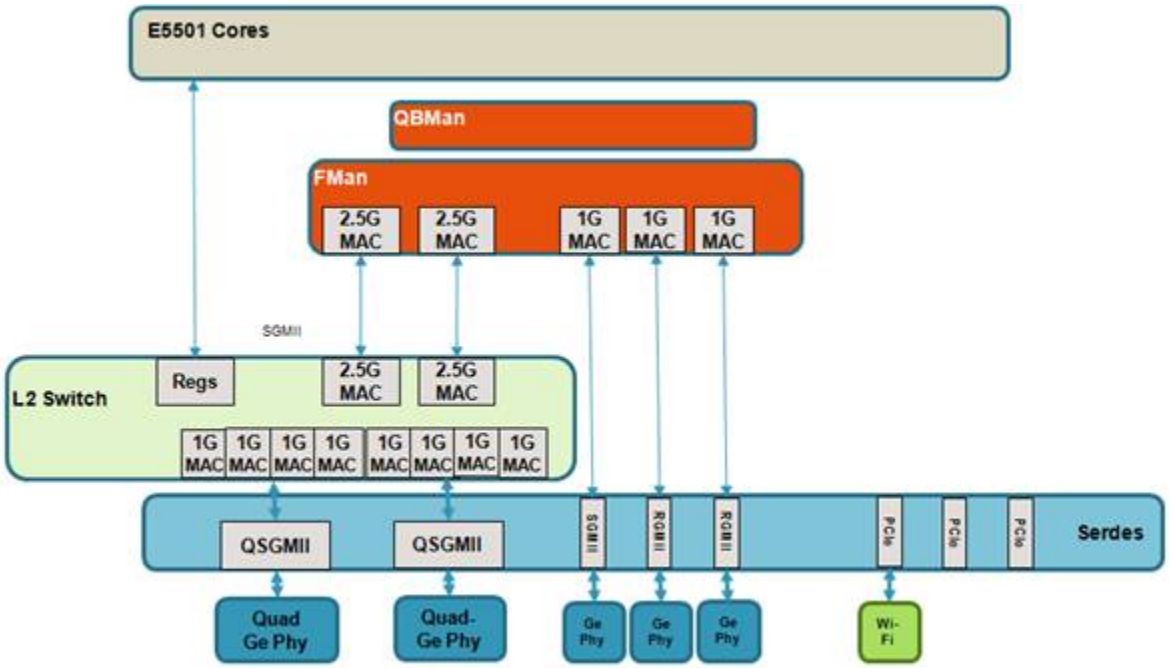
- For Linux: uImage-t1040d4rdb.bin and fsl-image-core-t1040d4rdb.ext2.gz.u-boot
- For ASF: uImage.ppce5500-asf and fsl-image-asf-t1040d4rdb.ext2.gz.u-boot

12.2.3.3.2 Test Procedure

This section describes the test procedure for various configurations of IPv4 IPSec forwarding

Test Configuration

T1040D4RDB have8 1Gb L2 switch ports which are external ports and 1 SGMII and 2 RGMII ports, like as followings:

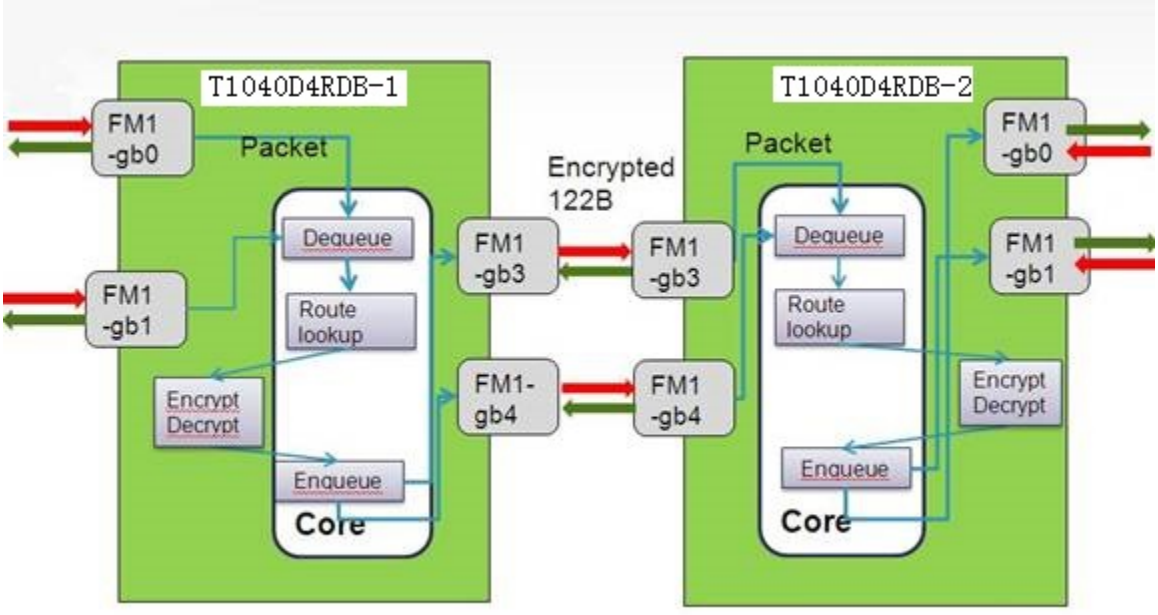


Note: two internal 2.5G mac of l2switch which connected to Fman's two 2.5G mac.

So traffic which will go through DPAA on T1040D4RDB will use following Ethernet interfaces for each board:

fm1-gb0(2.5G)/fm1-gb1(2.5G)/fm1-gb3(RGMII)/fm1-gb4(RGMII).

And the maximum traffic what we can inject to DPAA is 8Gbps. Thus, Linux/ASF/USDPAA IPv4 IPSec forward chooses four L2 switch ports and three SGMII/RGMII ports for benchmark test. The following diagram show traffic flow which will go through to DPAA:



4x1Gb Ethernet IPv4 IPSec Forward 128 flows(bi-directional) configuration:

Note: DMAC is mac address of fm1-gbx (0, 1, 3, 4) of T1040D4RDB board. Please make change based on target board.

- **Spirent Testcenter configuration for Linux IPv4 IPSec Forward:**
- Port 1 to T1040RDB-1 fm1-gb0 <1Gbps>:
  - Src: 192.85.1.2 – 192.85.1.9 -> Dst: 192.86.1.2 – 192.86.1.5

                done
            ;;
esac
```

- Copy above file to board
- On T1040D4RDB-1:

bash linux_ipsec_4g.sh left

- On T1040D4RDB-2:

bash linux_ipsec_4g.sh right

- **Configuration for ASF IPv4 forward on T1040D4RDB:**
- Configure ASF modules

#cd /usr/driver/asf/min

#insmod asf.ko

#insmod asfctrl.ko

insmod asfipsec.ko

insmod asfctrl_ipsec.ko

#echo 9000 > /sys/asfctrl/ffp/asfctrl_ffp_udp_tmout

#echo 0 > /proc/sys/net/core/xfrm_larval_drop

#cd /usr/driver/asf/scripts/fmc

#fmc -c asf-cfg-perf-2041.xml -p asf-fman-perf-policy.xml -s Soft_FragParser.xml –a

#echo 9000 > /proc/sys/net/netfilter/nf_conntrack_udp_timeout

#echo 9000 > /proc/sys/net/netfilter/nf_conntrack_udp_timeout_stream

- Configure L2switch settings
- • Refer to **Configure L2switch for Linux IPv4 Forward**
- Configure network settings for fm1-gb0 – fm1-gb4
- Refer to **Configure network settings for Linux IPv4 Forward**

Running the test

After Sprient Testcenter application configure completely, start pump traffic to measure IPv4 forward throughput.

Appendix

- Check L2switch status:

#l2sw_bin

mac dump

check

port stats all show

- type “?” to get more information in l2sw_bin

12.2.4 IPSec Forward - eTSEC

How to setup a board to baseline eTSEC IPSec performance for QorIQ processor development boards.

12.2.4.1 Test Environment

Baseline non-DPAA platform performance.

Benchmarking Objective

The purpose of this guide is to show how to setup a Linux IPsec system on a NXP QorIQ processor based system and how to measure its performance.

NOTE

LS1021ATWR was used for the demo. Please refer to the board's manual for other boards.

Hardware Platform Identification

Non-DPAA platforms:

- LS1021ATWR

For board switch settings, please see the corresponding reference manual. Operating frequencies (CPU, CCB, DDR) must be set to the highest allowed values (check the manual).

Network Simulator

Spirent Test Center Performance Analysis System

Spirent Testcenter v4.41.

Target Development System Software

Software Platform Identification

All software was built from the QorIQ SDK ISO.

Boot Loader

U-boot - configuration:

- Enable cacheline interleaving mode: CS0+CS1
- Enable DDR controller interleaving mode: cache line (if there are two DDR controllers)

Operating system

The BSP distribution includes source code for Linux vanilla kernel 4.1.8 and NXP-specific kernel patches. This is the default kernel package for the SDK configuration.

Root filesystem considerations

The IPsec testing procedure makes use of the “arp”, “ifconfig” and “ip” utilities. These are part of the net-tools and iproute2 packages, which should be included in the root filesystem.

12.2.4.2 Test Procedure

The test procedure for various configurations of IPv4 Sec & Forwarding. The LS1021ATWR platform is used as an example.

Test Configuration

The configuration used is detailed in Figure 1.

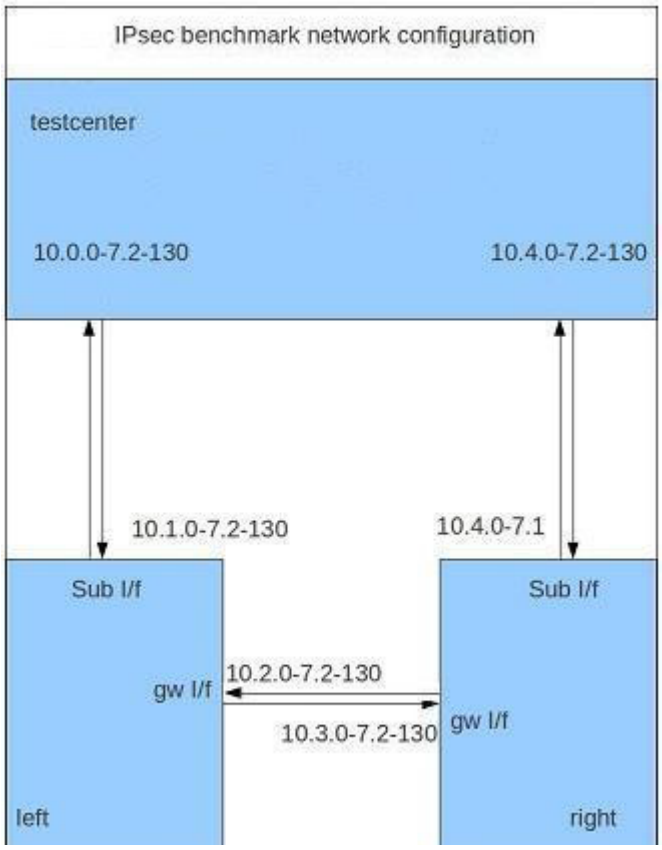

Figure 381. Multitunnel IPsec configuration

The number of flows is configurable. Please refer to the provided script (section "IPsec configuration script").

NOTE

In further sections, it is assumed that eth2 is used as subnet i/f, eth1 as gateway i/f and eth0 as boot i/f. If this is not the case, be careful to make all necessary changes (to the IPsec setup script, SMP affinities, etc.).

Spirent Test Center Configuration

- RFC2544 command sequencer (“Tools -> Wizards -> Benchmarking -> RFC2544”) and Test Center Reporter
- Performance-related parameters:

```
- Test Duration: 60 Seconds
- Resolution: 0.1%
- Packet Loss Rate: 0.001 %
- Frame Size: 82, 408, 1442 bytes
```

NOTE

The IPsec configuration script (section 4.1) sets the MTU to 2000 so that the 1518 bytes frames won’t be fragmented and reassembled.

Setup

- make sure that operating frequencies (CPU, CCB, DDR) are set to the highest allowed values (check the corresponding platform reference manual); for LS1021ATWR that would be (extracted from u-boot log):

```
CPU:   Freescale LayerScape LS1021E, Version: 2.0, (0x87081120)
Clock Configuration:
       CPU0(ARMV7):1000 MHz,
       Bus:300  MHz, DDR:800  MHz (1600 MT/s data rate)
```

- kernel configuration provided Linux kernel comes with a default configuration file,in order to obtain better performance, the following changes have to done:

```
CONFIG_NR_CPUS 2 (default: 4)
CONFIG_USB_SUPPORT disabled (default: builtin)
CONFIG_MMC disabled (default: builtin)
CONFIG_SOUND disabled (default: builtin)
```

- kernel boot parameters used:

```
root=/dev/ram rw console=ttyS0,115200 ramdisk_size=1000000 log_buf_len=128K
```

NOTE

Ramboot is preferred when performing benchmarking, since nfsboot might incur performance hit due to inherent network traffic

- kill all unneeded user space processes, for example:

```
/etc/init.d/sshd stop
/etc/init.d/xinetd stop
pid=`ps -ef | grep udhcpc | awk '{print $2}'` && kill -9 $pid
```

NOTE

The exact commands depend on the features included in the root filesystem.

- set hostname (needed so that we can use a single script for setting up IPsec on both boards)

```
o left board: hostname elmer
o right board: hostname donald
```

- set up IPsec by running the script provided in section "IPsec configuration script"
- set up SMP affinities for caam (due to the balanced job ring allocation mechanism, the settings might vary; below setup assumes there is an equal number of active sessions per job ring - such that Job Ring 0 is the first being picked - and that IPsec security associations are created alternatively, i.e. one SA for left-to-right direction, followed by one SA for right-to-left direction and so on)

```
o cat /proc/interrupts | grep jr
 74:          0          0       GIC 135 Level     1710000.jr
 75:          0          0       GIC 136 Level     1720000.jr
 76:          0          0       GIC 137 Level     1730000.jr
 77:          0          0       GIC 138 Level     1740000.jr

echo 1 > /proc/irq/74/smp_affinity
echo 1 > /proc/irq/76/smp_affinity
echo 2 > /proc/irq/75/smp_affinity
echo 2 > /proc/irq/77/smp_affinity
```

- set up SMP affinities for gianfar:

```
o cat /proc/interrupts | grep eth
 56:          0          0       GIC 176 Level     eth0_g0_tx
 57:          0          0       GIC 177 Level     eth0_g0_rx
 58:          0          0       GIC 178 Level     eth0_g0_er
 59:          0          0       GIC 179 Level     eth0_g1_tx
 60:          0          0       GIC 180 Level     eth0_g1_rx
 61:          0          0       GIC 181 Level     eth0_g1_er
 62:          0          0       GIC 182 Level     eth1_g0_tx
 63:          0          0       GIC 184 Level     eth1_g0_rx
 64:          0          0       GIC 185 Level     eth1_g0_er
 65:          0          0       GIC 186 Level     eth1_g1_tx
 66:          0          0       GIC 187 Level     eth1_g1_rx
 67:          0          0       GIC 188 Level     eth1_g1_er
 68:          0          0       GIC 189 Level     eth2_g0_tx
 69:         66          0       GIC 190 Level     eth2_g0_rx
 70:          0          0       GIC 191 Level     eth2_g0_er
 71:          0          0       GIC 192 Level     eth2_g1_tx
 72:          0          0       GIC 193 Level     eth2_g1_rx
 73:          0          0       GIC 194 Level     eth2_g1_er
o left board
echo 1 > /proc/irq/62/smp_affinity
echo 1 > /proc/irq/69/smp_affinity
echo 2 > /proc/irq/63/smp_affinity
echo 2 > /proc/irq/68/smp_affinity
o right board
echo 1 > /proc/irq/63/smp_affinity
echo 1 > /proc/irq/68/smp_affinity
echo 2 > /proc/irq/62/smp_affinity
echo 2 > /proc/irq/69/smp_affinity
```

NOTE

The SMP affinities setup is not identical on left and right board. The idea is to process left -> right flows on CPU0 and right -> left flows on CPU1.

- tune gianfar settings

```
ethtool -C eth1 rx-frames 12 rx-usecs 32
ethtool -C eth1 tx-frames 12 tx-usecs 32
ethtool -G eth1 rx 128 tx 128
ethtool -C eth2 rx-frames 12 rx-usecs 32
ethtool -C eth2 tx-frames 12 tx-usecs 32
ethtool -G eth2 rx 128 tx 128
```

- other optimizations

```
sysctl -w net.ipv4.conf.default.rp_filter=0
sysctl -w net.ipv4.conf.all.rp_filter=0
ifconfig eth0 down
```

Results

If performance is measured by using the TestCenter RFC 2544 Command Sequencer, results will be displayed in Spirent TestCenter Results Reporter.

IPSec Configuration Script

The script below creates a configurable number of IPsec tunnels (up to 1024), depending on the values of i_max and j_max. Currently, the script uses 3DES-CBC-HMAC-SHA1 as AEAD mode. This can be changed by editing the auth and enc parameters in mkstate() function. Also note that the network interfaces (left_sub_if, left_gw_if, right_sub_if, right_gw_if) and their MAC addresses must be modified according to your HW setup. MTU is set to 2000 bytes (instead of default 1500) so that 1500 bytes frames won't be fragmented (and reassembled at the other end).

```
#!/bin/bash
#ESP
function mkstate() {
    ip xfrm state add \
    src $2 dst $3 \
    proto esp spi $6 mode $5 \
    auth "hmac(sha1)" $8 \
    enc "cbc(des3_ede)" $7 \
    sel src 0.0.0.0/0 dst 0.0.0.0/0
}
function mkpolicy() {
    ip xfrm policy add \
    dir $6 src $1 dst $4 \
    tmpl src $2 dst $3 \
    proto esp mode $5
}
#
# usage: mktunnel src-netspec src-gw dst-gw dst-netspec
# e.g. mktunnel 192.168.2.0/24 192.168.3.1 192.168.3.2 192.168.4.2 <tunnel/transport>
#
function mktunnel() {
    base_lr=`echo $1-$2-$3-$4 | md5sum`
    base_rl=`echo $4-$3-$2-$1 | md5sum`

    # try and generate a %8x spi and gen keys for the 'left'.
    # seen complaints from leading zeros in an SPI, so cut them out, too.
    spi_lr=`echo $base_lr | tr -d 0 | tr -d a-f | cut -c -8`
    auth_key_lr=`echo $base_lr | cut -c -20`
    cipher_key_lr=`echo $base_lr | cut -c -24`
    mkstate $1 $2 $3 $4 $5 $spi_lr $cipher_key_lr $auth_key_lr
    # now the 'right'
    spi_rl=`echo $base_rl | tr -d 0 | tr -d a-f | cut -c -8`

    auth_key_rl=`echo $base_rl | cut -c -20`
    cipher_key_rl=`echo $base_rl | cut -c -24`
    mkstate $4 $3 $2 $1 $5 $spi_rl $cipher_key_rl $auth_key_rl
    ip addr show | awk '/inet/ {print $2}' | grep $2
    if [ $? == 0 ]
    then
        echo this host is the left
        mkpolicy $1 $2 $3 $4 $5 out
        mkpolicy $4 $3 $2 $1 $5 in
        mkpolicy $4 $3 $2 $1 $5 fwd
    else
        echo this host is the right
        mkpolicy $1 $2 $3 $4 $5 in
        mkpolicy $1 $2 $3 $4 $5 fwd
        mkpolicy $4 $3 $2 $1 $5 out
    fi
}

echo 1 > /proc/sys/net/ipv4/ip_forward
```

```
ip xfrm state flush
ip xfrm policy flush

12.2.5 Netperf

Provides details for reproducing NetPerf performance results. The objectives are to baseline Netperf performance and identify optimizations and implement these improvements on the QorIQ DPAA platform.

12.2.5.1 Test Environment

Benchmarking Objectives

The purpose of this guide is to show how to setup a Netperf system on a NXP QorIQ processor based system and how to measure its performance.

NOTE

P4080DS was used for the demo. Please refer to the board's manual for other boards.

Platform Configurations

Table 607. Software Platform Identification

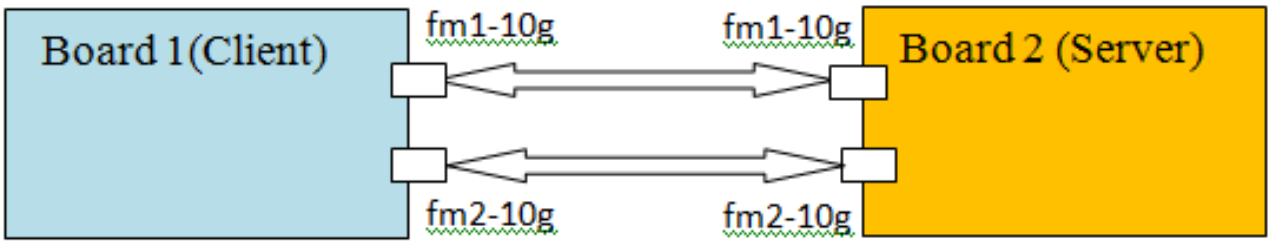
System Software	Description
Host Development System Software	Yocto
Target Development System: Boot Loader	U-boot 2016.01 with default ddr configurations
Target Development System: OS	• Kernel built based on default kernel configuration and enable CONFIG_DPAA_ETH_OPTIMIZE_FOR_TERM option • Default ramdisk rootfs coming with SDK v2.0 ISO
Application	The tests procedure for Netperf makes use of the "netserver", "netperf" and “ifconfig” utilities. These are part of the netperf and net-tools packages respectively, which are included the root file system.

12.2.5.2 Test Procedure

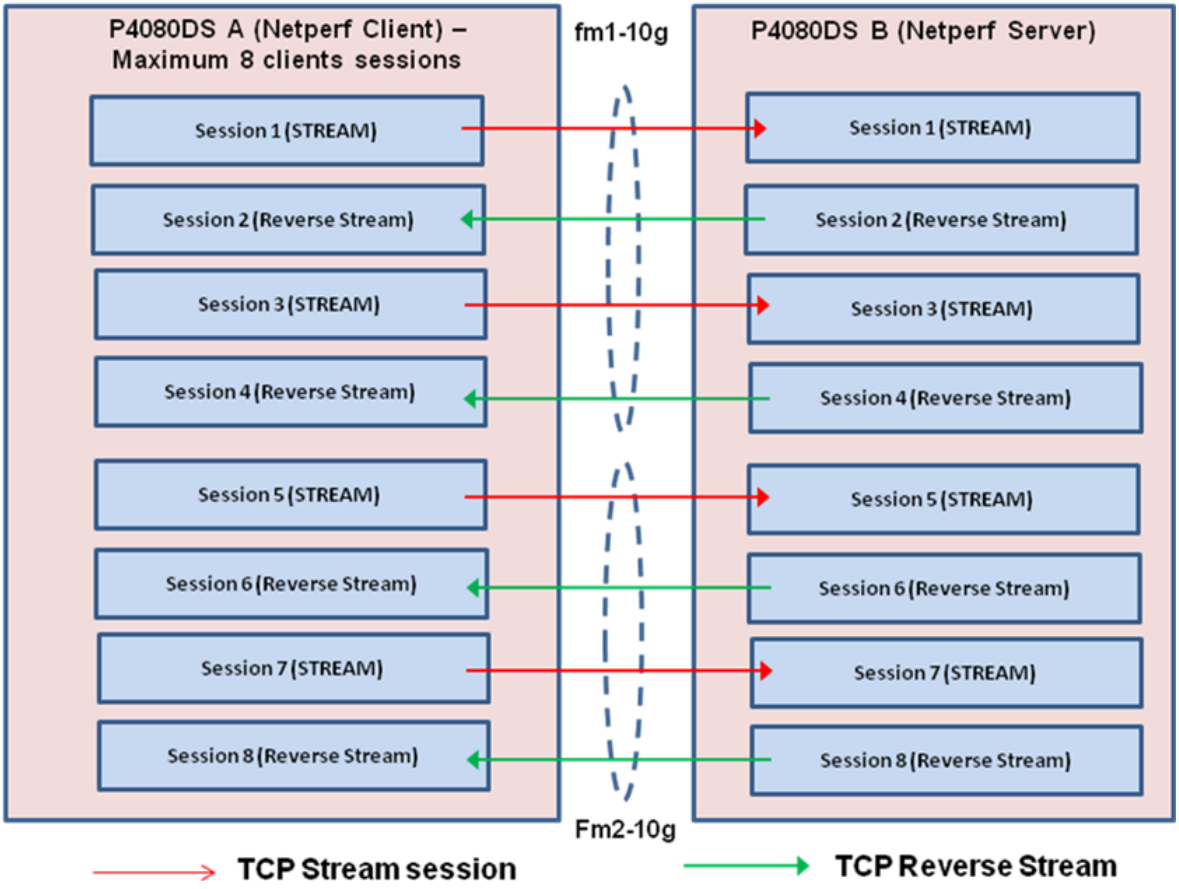
The P4080 was the first NXP SoC to incorporate the DPAA. As such, it is used in this examples. However, test methodology is intended to apply in the same manner to all DPAA-based SoCs.

Test Procedure: Test Bed Description

The test environment comprises two systems running Linux to be connected back-to-back. One is running Netperf server and the other is running Netperf client. The Netperf client is P4080DS and the Netperf server is another P4080DS or a Linux PC. The figure below shows two P4080DS connected back-to-back:



The software setup for the P4080DS is shown in the figure below:



Running Test and Result Collection: P4080DS or Linux PC Netperf Server Example

P4080DS or Linux PC works as Netperf server (netserver). Steps are as followings:

1. Set IP address

```
# ifconfig fm1-10g:1 1.0.0.1
# ifconfig fm1-10g:2 2.0.0.1
```

```
# ifconfig fm1-10g:3 3.0.0.1
# ifconfig fm1-10g:4 4.0.0.1
# ifconfig fm2-10g:5 5.0.0.1
# ifconfig fm2-10g:6 6.0.0.1
# ifconfig fm2-10g:7 7.0.0.1
# ifconfig fm2-10g:8 8.0.0.1
```

2. Configure fmc PCD files: (not required for Linux PC)

```
# fmc -c cfg_P4080DS_20g.xml -p policy_P4080DS.xml -a
```

3. Start netserver:

```
# netserver -L 1.0.0.1 0 -p 30001
# netserver -L 2.0.0.1 0 -p 30002
# netserver -L 3.0.0.1 0 -p 30003
# netserver -L 4.0.0.1 0 -p 30004
# netserver -L 5.0.0.1 0 -p 30005
# netserver -L 6.0.0.1 0 -p 30006
# netserver -L 7.0.0.1 0 -p 30007
# netserver -L 8.0.0.1 0 -p 30008
```

Running Test and Result Collection: P4080DS Netperf Client Mode Example

Another P4080DS works as Netperf client (netperf). Steps are as followings:

1. Set IP address

```
# ifconfig fm1-10g:1 1.0.0.2
# ifconfig fm1-10g:2 2.0.0.2
# ifconfig fm1-10g:3 3.0.0.2
# ifconfig fm1-10g:4 4.0.0.2
# ifconfig fm2-10g:5 5.0.0.2
# ifconfig fm2-10g:6 6.0.0.2
# ifconfig fm2-10g:7 7.0.0.2
# ifconfig fm2-10g:8 8.0.0.2
```

2. Configure fmc PCD files:

```
# fmc -c cfg_P4080DS_20g.xml -p policy_P4080DS.xml -a
```

3. Start netperf on client:

```
# netperf -Cc -H 1.0.0.1 -l 60 -p 30001 -t TCP_STREAM -T 1,1 -P 0 -B "outbound" -- -m 16384 &
# netperf -Cc -H 2.0.0.1 -l 60 -p 30002 -t TCP_MAERTS -T 2,2 -P 0 -B "inbound" -- -m 16384 &
# netperf -Cc -H 3.0.0.1 -l 60 -p 30003 -t TCP_STREAM -T 3,3 -P 0 -B "outbound" -- -m 16384 &
# netperf -Cc -H 4.0.0.1 -l 60 -p 30004 -t TCP_MAERTS -T 4,4 -P 0 -B "inbound" -- -m 16384 &
# netperf -Cc -H 5.0.0.1 -l 60 -p 30005 -t TCP_STREAM -T 5,5 -P 0 -B "outbound" -- -m 16384 &
# netperf -Cc -H 6.0.0.1 -l 60 -p 30006 -t TCP_MAERTS -T 6,6 -P 0 -B "inbound" -- -m 16384 &
# netperf -Cc -H 7.0.0.1 -l 60 -p 30007 -t TCP_STREAM -T 7,7 -P 0 -B "outbound" -- -m 16384 &
# netperf -Cc -H 8.0.0.1 -l 60 -p 30008 -t TCP_MAERTS -T 0,0 -P 0 -B "inbound" -- -m 16384 &
```

NOTE: replace the value ‘64’ of ‘-m’ option with below values to test other send message sizes:
64/128/256/512/1024/1440/1518/4172/9576/16384/32768/65535

To test default send message size, just remove the ‘-m 64’ option.

12.2.6 DPAA NAT and Firewall

How to setup the board to reproduce NAT and Firewall benchmark results for the QorIQ SDK boards.

12.2.6.1 Hardware

Benchmarking Objectives

The purpose of this guide is to show how to setup a NAT and Firewall system on a NXP QorIQ processor based system and how to measure its performance.

NOTE

P4080DS was used for the demo. Please refer to the board's manual for other boards.

The relevant QorIQ development systems covered

- P2040RDB
- P3041DS
- P4080DS (focus of this example)
- P5020DS
- P5040DS
- B4860QDS
- T4240QDS
- T4240RDB
- T2080QDS
- T2080RDB
- T1023RDB
- T1024RDB
- T1040RDB
- T1042RDB

Hardware Platform Identification

1. **P2040RDB**
   - Board: P2040RDB, CPLD version: 2.2
   - CPU: P2040E, Version: 2.0
   - Core: E500MC, Version: 3.2
   - Clock Configuration:
     - CPU0: 1200 MHz, CPU1:1200 MHz, CPU2:1200 MHz, CPU3:1200 MHz,
     - CCB: 600 MHz,
     - DDR: 600 MHz (1200 MT/s data rate) (Asynchronous), LBC:75 MHz
     - FMAN1: 500 MHz
   - 3 on-board SGMII ports and 2 on-board RGMII ports
2. **P3041DS**
   - Board: P3041DS, Sys ID: 0x1c, Sys Ver: 0x11, FPGA Ver: 0x05

- CPU: P3041E, Version: 2.0
- Core: E500MC, Version: 2.2
- Clock Configuration:
  - CPU0: 1500 MHz, CPU1:1500 MHz, CPU2:1500 MHz, CPU3:1500 MHz
  - CCB: 750 MHz
  - DDR: 666.667 MHz (1333.333 MT/s data rate) (Asynchronous), LBC:93.750 MHz
  - FMAN1: 583.333 MHz
- 1SGMII riser card with 3 Ethernet ports and 2 on-board RGMII ports
- 1 10G XAUI riser card
- PCIe e1000 NIC

3. **P4080DS**
   - Board: P4080DS, Sys ID: 0x17, Sys Ver: 0x01, FPGA Ver: 0x0c
   - CPU: P4080E, Version: 3.0
   - Core: E500MC, Version: 3.1
   - Clock Configuration:
     - CPU0: 1499.985 MHz, CPU1:1499.985 MHz, CPU2:1499.985 MHz, CPU3:1499.985 MHz
     - CPU4: 1499.985 MHz, CPU5:1499.985 MHz, CPU6:1499.985 MHz, CPU7:1499.985 MHz
     - CCB: 799.992 MHz
     - DDR: 649.994 MHz (1299.987 MT/s data rate) (Asynchronous), LBC:99.999 MHz
     - FMAN1: 599.994 MHz
     - FMAN2: 599.994 MHz
   - 1 SGMII riser card with 4 Ethernet ports
   - 2 10G XAUI riser cards
4. **P5020DS**
   - Board: P5020DS, Sys ID: 0x1c, Sys Ver: 0x01, FPGA Ver: 0x03
   - CPU: P5020E, Version: 2.0
   - Core: E5500, Version: 1.2
   - Clock Configuration:
     - CPU0: 2000 MHz, CPU1:2000 MHz
     - CCB: 800 MHz
     - DDR: 666.667 MHz (1333.333 MT/s data rate) (Asynchronous), LBC:100 MHz
     - FMAN1: 600 MHz
   - 1 SGMII riser card with 3 Ethernet ports and 2 on-board RGMII ports
   - 1 10G XAUI riser card
   - PCIe e1000 NIC
5. **P5040DS**
   - Board: P5040DS, Sys ID: 0x20, Sys Ver: 0x02, FPGA Ver: 0x02
   - CPU: P5040E, Version: 2.1

- Core: E5500, Version: 1.2
- Clock Configuration:
  - CPU0: 2266.667 MHz, CPU1:2266.667 MHz, CPU2:2266.667 MHz, CPU3:2266.667 MHz
  - CCB: 800 MHz
  - DDR: 800 MHz (1600 MT/s data rate) (Asynchronous), LBC:100 MHz
  - FMAN1: 600 MHz
  - FMAN2: 600 MHz
- 2 SGMII riser cards with 2 Ethernet ports on each and 2 on-board RGMII ports
- 2 10G XAUI riser cards
- PCIe e1000 NIC

6. **B4860QDS**
   - Board: B4860QDS, Sys ID: 0x21, Sys Ver: 0x12
   - CPU: B4860E, Version: 2.2
   - Core: E6500, Version: 2.0
   - Clock configuration:
     - CPU0: 1600 MHz, CPU1:1600 MHz, CPU2:1600 MHz, CPU3:1600 MHz
     - CCB: 666.667 MHz
     - DDR: 933.333 MHz (1866.667 MT/s data rate) (Asynchronous), IFC:166.667 MHz
     - FMAN1: 666.667 MHz
   - 2 on-board SGMII ports
   - 2 10G XFI ports
7. **T4240QDS**
   - Board: T4240QDS, Sys ID: 0x1e, Sys Ver: 0x22
   - CPU: T4240E, Version: 2.0
   - Core: E6500, Version: 2.0
   - Clock configuration:
     - CPU0: 1666.667 MHz, CPU1:1666.667 MHz, CPU2:1666.667 MHz, CPU3:1666.667 MHz
     - CPU4: 1666.667 MHz, CPU5:1666.667 MHz, CPU6:1666.667 MHz, CPU7:1666.667 MHz
     - CPU8: 1666.667 MHz, CPU9:1666.667 MHz, CPU10:1666.667 MHz, CPU11:1666.667 MHz
     - CCB: 733.333 MHz
     - DDR: 933.333 MHz (1866.667 MT/s data rate) (Asynchronous), IFC:183.333 MHz
     - FMAN1: 733.333 MHz
     - FMAN2: 733.333 MHz
   - 2 on-board RGMII ports
   - 4 10G XAUI riser cards
   - PCIe e1000 NIC
8. **T4240RDB**
   - Board: T4240RDB, Board rev: 0x04 CPLD ver: 0x0401

- CPU: T4240E, Version: 2.0
- Core: E6500, Version: 2.0
- Clock configuration:
  - CPU0: 1666.667 MHz, CPU1:1666.667 MHz, CPU2:1666.667 MHz, CPU3:1666.667 MHz
  - CPU4: 1666.667 MHz, CPU5:1666.667 MHz, CPU6:1666.667 MHz, CPU7:1666.667 MHz
  - CPU8: 1666.667 MHz, CPU9:1666.667 MHz, CPU10:1666.667 MHz, CPU11:1666.667 MHz
  - CCB: 733.333 MHz
  - DDR: 933.333 MHz (1866.667 MT/s data rate) (Asynchronous), IFC:183.333 MHz
  - FMAN1: 733.333 MHz
  - FMAN2: 733.333 MHz
- 8 on-board SGMII ports
- 4 10G XFI ports
- PCIe e1000 NIC

9. **T2080QDS**
   - Board: T2080QDS, Sys ID: 0x28, Board Arch: V1, Board Version: A
   - CPU: T2080E, Version: 1.1
   - Core: E6500, Version: 2.0
   - Clock configuration:
     - CPU0: 1800 MHz, CPU1:1800 MHz, CPU2:1800 MHz, CPU3:1800 MHz
     - CCB: 700 MHz
     - DDR: 933.333 MHz (1866.667 MT/s data rate) (Asynchronous), IFC:175 MHz
     - FMAN1: 700 MHz
   - 2 on-board RGMII ports
   - 4 10G XFI ports
   - PCIe e1000 NIC
10. **T2080RDB**
    - Board: T2080RDB, Board rev: 0x01 CPLD ver: 0x03
    - CPU: T2080E, Version: 1.1
    - Core: E6500, Version: 2.0
    - Clock configuration:
      - CPU0: 1799.820 MHz, CPU1:1799.820 MHz, CPU2:1799.820 MHz, CPU3:1799.820 MHz
      - CCB: 599.940 MHz
      - DDR: 799.980 MHz (1599.960 MT/s data rate) (Asynchronous), IFC:149.985 MHz
      - FMAN1: 699.930 MHz
    - 2 on-board RGMII ports
    - 2 10G XFI ports
    - 2 10G BaseT ports
    - PCIe e1000 NIC

11. **T1023RDB**
    - Board: T1023RDB
    - CPU: T1023E, Version: 1.0
    - Core: E5500, Version: 2.1
    - Clock configuration:
      - CPU0: 1400 MHz, CPU1:1400 MHz
      - CCB: 400 MHz
      - DDR: 800 MHz (1600 MT/s data rate) (Asynchronous), IFC:100 MHz
      - FMAN1: 700 MHz
    - 1 on-board RGMII ports
    - 1 on-board SGMII ports
    - 1 2.5G SGMII port
    - PCIe e1000 NIC
12. **T1024RDB**
    - Board: T1024RDB, Board rev: 0x01 CPLD ver: 0x02
    - CPU: T1024E, Version: 1.0
    - Core: E5500, Version: 2.1
    - Clock configuration:
      - CPU0: 1400 MHz, CPU1:1400 MHz
      - CCB: 400 MHz
      - DDR: 800 MHz (1600 MT/s data rate) (Asynchronous), IFC:100 MHz
      - FMAN1: 700 MHz
    - 2 on-board RGMII ports
    - 1 10G BaseT port or 1 2.5G SGMII port
    - PCIe e1000 NIC
13. **T1040RDB**
    - Board: T1040RDB, Board rev: 0x01 CPLD ver: 0x06
    - CPU: T1040E, Version: 1.1
    - Core: E5500, Version: 2.1
    - Clock configuration:
      - CPU0: 1400 MHz, CPU1:1400 MHz, CPU2:1400 MHz, CPU3:1400 MHz
      - CCB: 600 MHz
      - DDR: 800 MHz (1600 MT/s data rate) (Asynchronous), IFC:150 MHz
      - FMAN1: 600 MHz
    - 2 on-board RGMII ports and 1 on-board SGMII ports
    - 8 QSGMII ports for L2-Switch
    - PCIe e1000 NIC
14. **T1042RDB**

- Board: T1042RDB, Board rev: 0x01 CPLD ver: 0x08
- CPU: T1042E, Version: 1.1
- Core: E5500, Version: 2.1
- Clock configuration:
  - CPU0: 1200 MHz, CPU1:1200 MHz, CPU2:1200 MHz, CPU3:1200 MHz
  - CCB: 500 MHz
  - DDR: 800 MHz (1600 MT/s data rate) (Asynchronous), IFC:125 MHz
  - FMAN1: 500 MHz
- 2 on-board RGMII ports
- PCIe e1000 NIC

Network Simulator

- Spirent Testcenter version: 4.41
- Choose Bound Stream Block for Traffic generator
- Choose Wizard -> Custom Test -> Throughput from Spirent Testcenter to create command sequencer for throughput test
- Testcenter configuration:
  - Test Duration: 60 Seconds
  - Resolution: 0.1%
  - Packet Loss Rate: 0.001 %
  - Packet Size: 64, 128, 256, 512, 1024, 1280, 1518 bytes

Target Development System Software

Boot loader

Default u-boot can be used for this benchmark test.

FMAN ucode

The SDK ISO contains the default ucode versions for all the supported platforms. Please refer to the “Linux Kernel and Device Drivers” section from the “Components” documentation chapter.

Linux Kernel

The default kernel in ISO doesn't enable NAT/Firewall feature, so it need manually configure kernel. The steps for building the kernel is listed below.

Additional root filesystem considerations

The tests procedure for NAT/Firewall makes use of the "arp", "ifconfig" and “ip” utilities. These are part of the net-tools and iproute2 packages, which the root filesystem stored in the hard disk should have.

12.2.6.2 Kernel

Kernel Configuration to add support for NAT and Firewall.

Kernel Configuration to add support for NAT and Firewall

            <*>   ARP packet filtering
            <*>   ARP payload mangling
```

Prepare ramdisk

Select the following packages when build ramdisk:

- `[*] busybox(busybox.config)`
- `[*] ethtool`
- `[*] net-tools`
- `[*] iptables`

Make sure BusyBox Configuration includes following changes under Networking Utilities:

- `[*]arping`
- `[*]ftpget`
- `[*]ftpput`
- `[*]hostname`
- `[*]ifconfig`
- `[*]Enable status reporting output (+7k)`

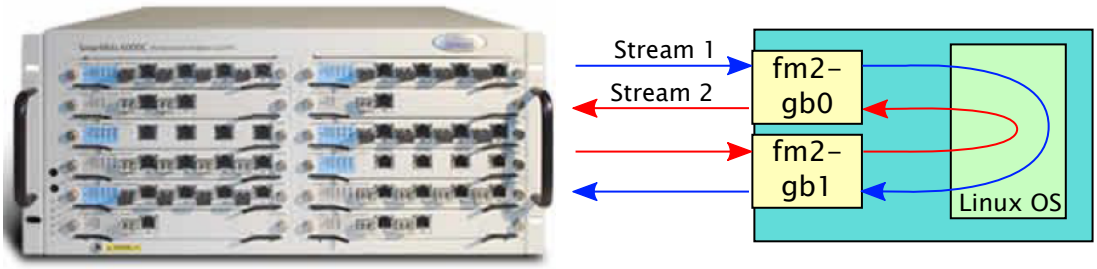
- `[*]Enable option "hw" (ether only)`
- `[*]ifupdown`
- `[*]arping`
- `[*]Use ip applet`
- `[*]tftp`
- `[*]Enable "get" command`
- `[*]Enable "put" command`
- `[*]ifupdown`

12.2.6.3 Test Setup

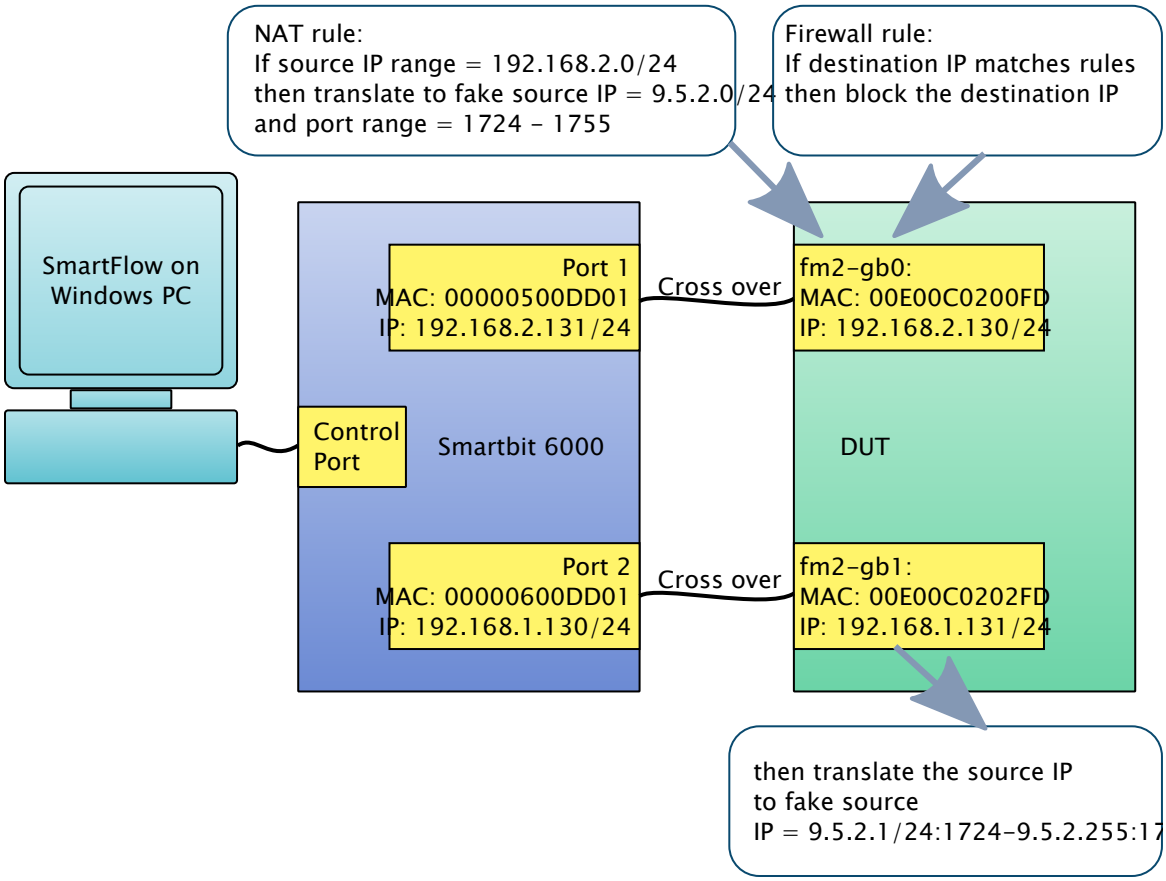
Running the DPAA performance benchmark test

Typical Test Setup

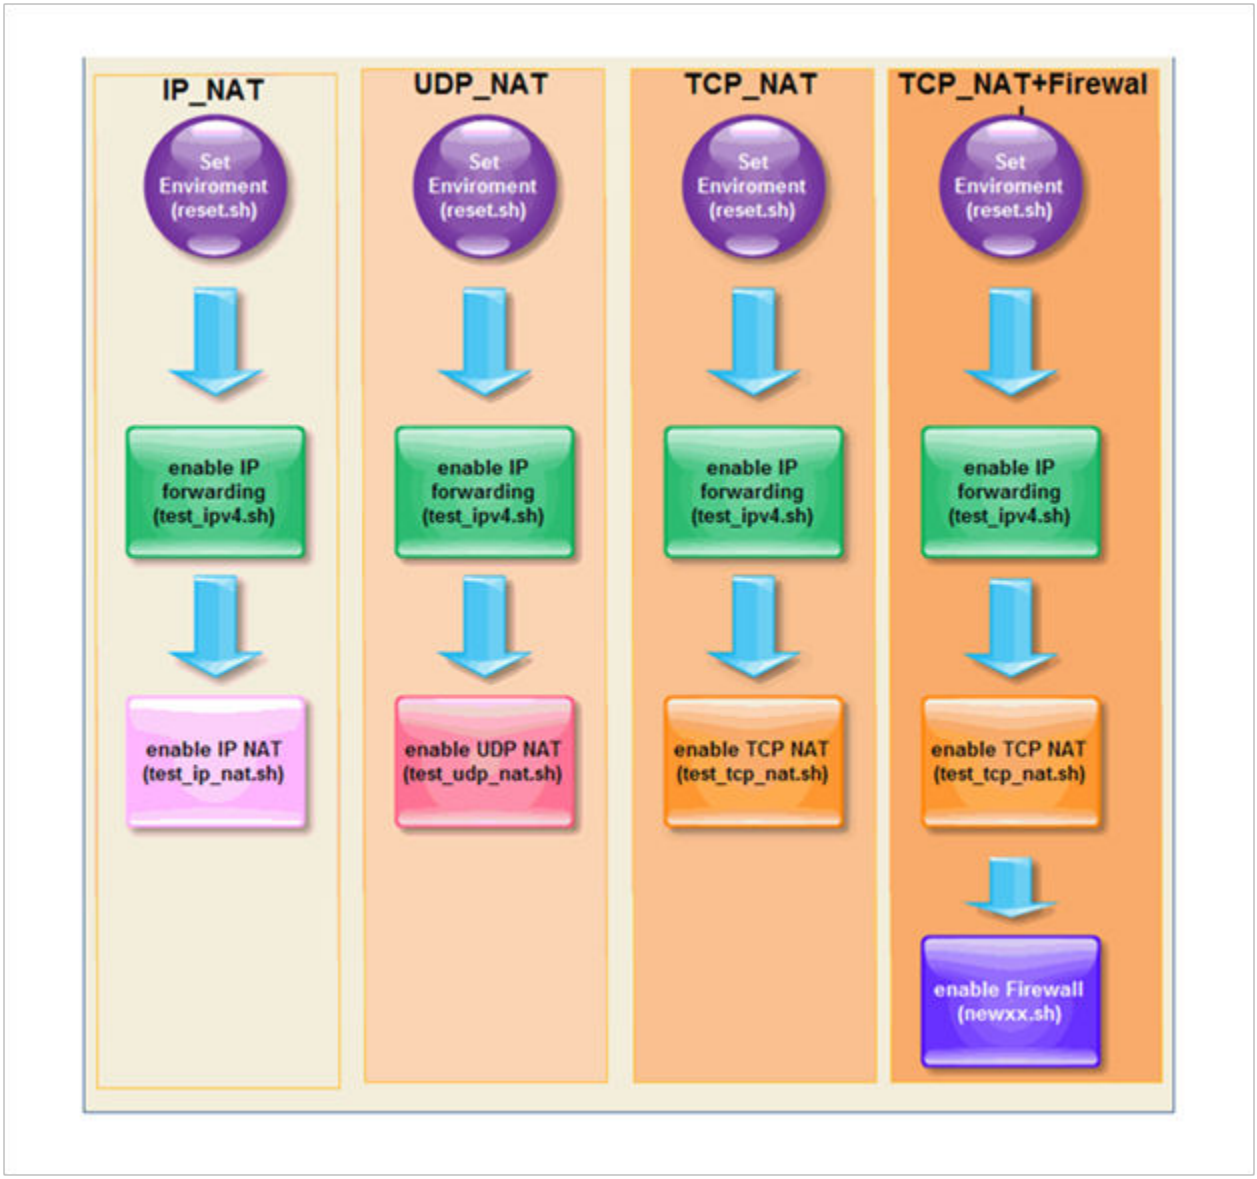
- Uni-directional (1 flow) = Stream 1
- Bi-directional (2 flow) = Stream 1 + Stream 2



NAT and Firewall Test Setup



Test Procedure



- Use reset.sh to set the environment which is included Source IP range, Fake IP range, income network device, output network device, then flush all rules in those tables and set the default policy for the tables.
- Use `test_ipv4.sh` to set QorIQ_USDK board IP address, do smartbit MAC and IP binding, and then enable IP Forwarding.
- Use `test_xxx_NAT.sh` to enable NAT translate.
- Use `newxxx.sh` to enable Firewall. `New1.sh` means 1 rule, `new128.sh` means 128 rules, `new1024.sh` means 1024 rules.

Test Tips

We can use the following commands to check if the setting is correct.:

```
iptable -L -t nat     #check the rule for the nat

tcpdump -i fm2-gb0    #dump the output interface to check the source ip addr was changed according
the nat rule.
```

```
iptable -L            #check the filter rules we created.
```

12.2.6.4 Test Demos

Example Test Demo and scripts to setup the board and to reproduce NAT and Firewall benchmark results.

Test Demos

Example Test Demo and scripts to setup the board and to reproduce NAT and Firewall benchmark results are provided below.

12.2.7 eTSEC NAT and Firewall

How to setup the board to reproduce NAT and Firewall benchmark results for the QorIQ USDK boards.

12.2.7.1 Hardware

Benchmarking Objectives

The purpose of this guide is to show how to setup NAT and Firewall on a NXP QorIQ processor based system and how to measure its performance.

NOTE

LS1021ATWR was used for the demo. Please refer to the board's manual for other boards.

The relevant QorIQ development systems covered

- LS1021ATWR

Hardware Platform Identification

Table 608. LS1021ATWR SoC Clock Settings

Core/CPU (MHz)	CCB (MHz)	DDR (MHz)
1000	300	800

Flashing U-boot on LS1021ATWR

- `tftpboot 0x81000000 u-boot.bin`
- `protect off 0x64100000 +$filesize`
- `erase 0x64100000 +$filesize;`
- `cp.b 1000000  0x64100000 $filesize;`
- `protect on 0x64100000 +$filesize;`
- `cmp.b  1000000 0x64100000 $filesize`

Flashing RCW on LS1021ATWR

- `tftpboot 0x81000000 u-boot.bin`
- `protect off 0x64000000 +$filesize`
- `erase 0x64000000 +$filesize;`
- `cp.b 1000000  0x64000000 $filesize;`
- `protect on 0x64000000 +$filesize;`
- `cmp.b  1000000 0x64000000 $filesize`

Environmental Variables and boot up kernel

- ```
  setenv ipaddr 10.192.208.162
  ```
- ```

12.2.7.2 Kernel

The kernel is prepared and configured to run the eTSEC performance benchmark on QorIQ boards.

Preparing the Kernel on LS1021ATWR: Config Kernel

Kernel Configure Tree View Options, this is only a demo, please enable the kernel NAT/Firewall options as more as possible according to the kernel version.

                <*>   ARP packet filtering
                <*>   ARP payload mangling
```

```
Gianfar Ethernet (CONFIG_GIANFAR):
Location:
    -> Device Drivers
       -> Network device support (NETDEVICES [=y])
         -> Ethernet driver support (ETHERNET [=y])
           -> Freescale devices (NET_VENDOR_FREESCALE [=y])
```

Preparing the Kernel on LS1021ATWR: Kernel config Tips

Use the default kernel config then enable almost all NAT/Firewall features as the NAT/Firewall config.

Prepare ramdisk on LS1021ATWR

Select the following packages when build ramdisk:

-
```
[*] busybox(busybox.config)
```

-
```
[*] ethtool
```

- `[*] net-tools`
- `[*] iptables`

Make sure BusyBox Configuration includes following changes under Networking Utilities:

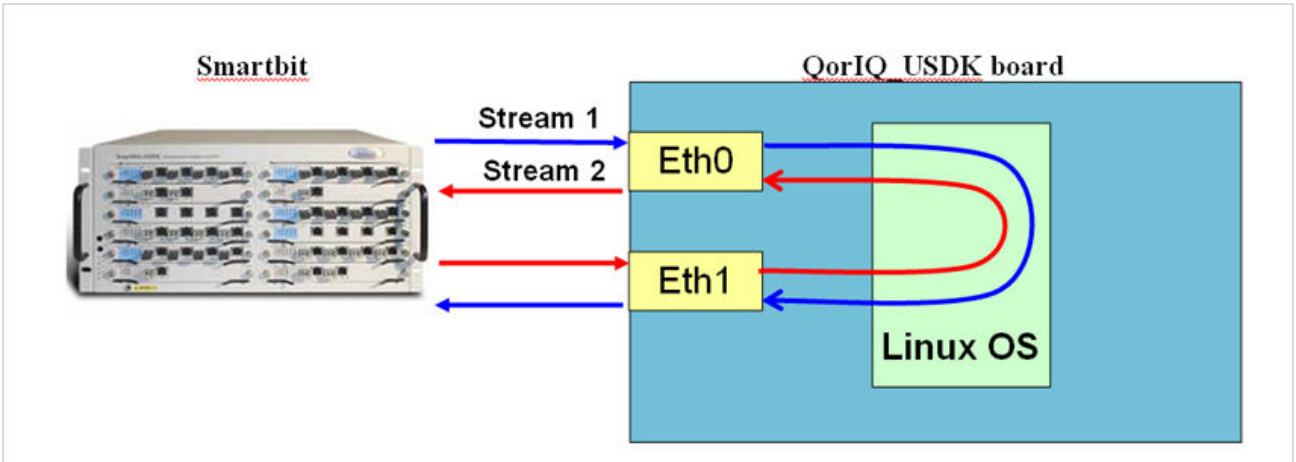
- `[*]arping`
- `[*]ftpget`
- `[*]ftpput`
- `[*]hostname`
- `[*]ifconfig`
- `[*]Enable status reporting output (+7k)`
- `[*]Enable option "hw" (ether only)`
- `[*]ifupdown`
- `[*]arping`
- `[*]Use ip applet`
- `[*]tftp`
- `[*]Enable "get" command`
- `[*]Enable "put" command`
- `[*]ifupdown`

12.2.7.3 Test Setup

Running the eTSEC performance benchmark test

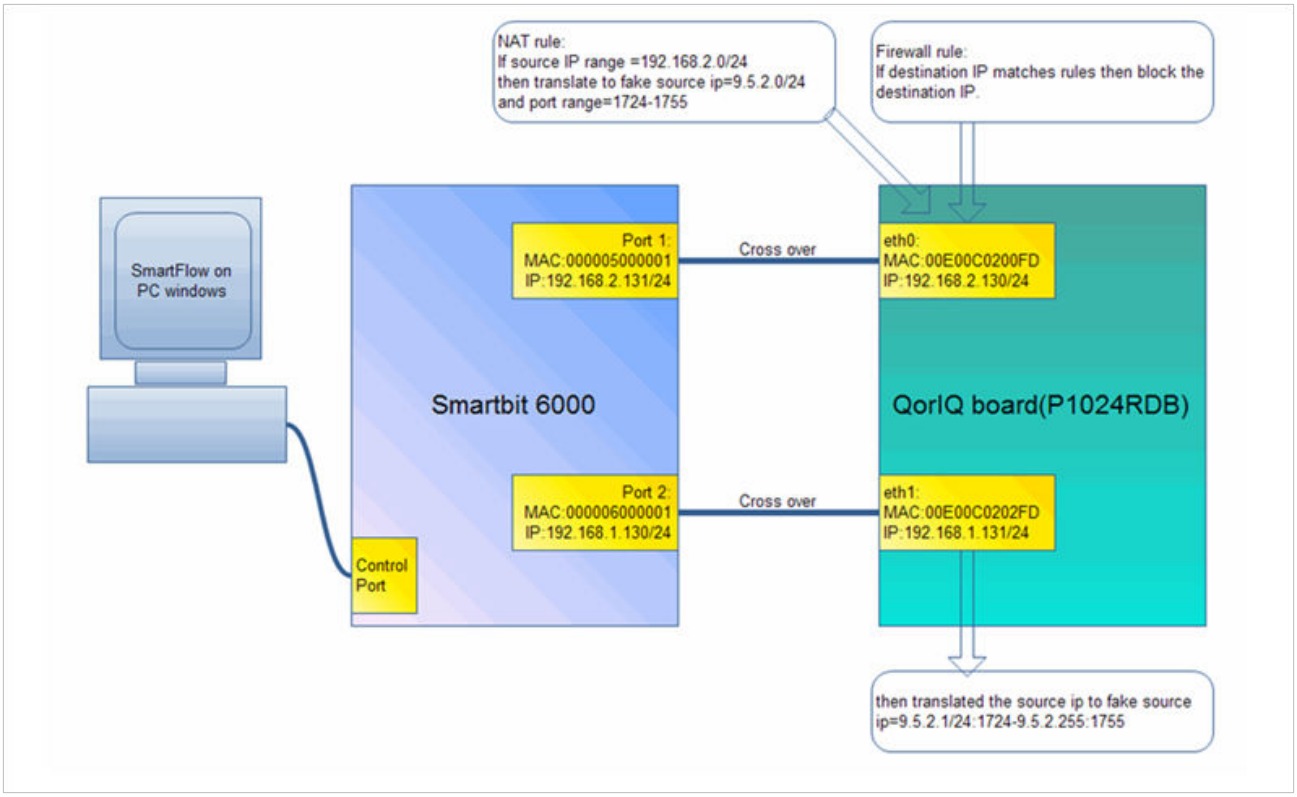
Typical Test Setup on LS1021ATWR

- Uni-directional (1 flow) = Stream 1
- Bi-directional (2 flow) = Stream 1 + Stream 2
-

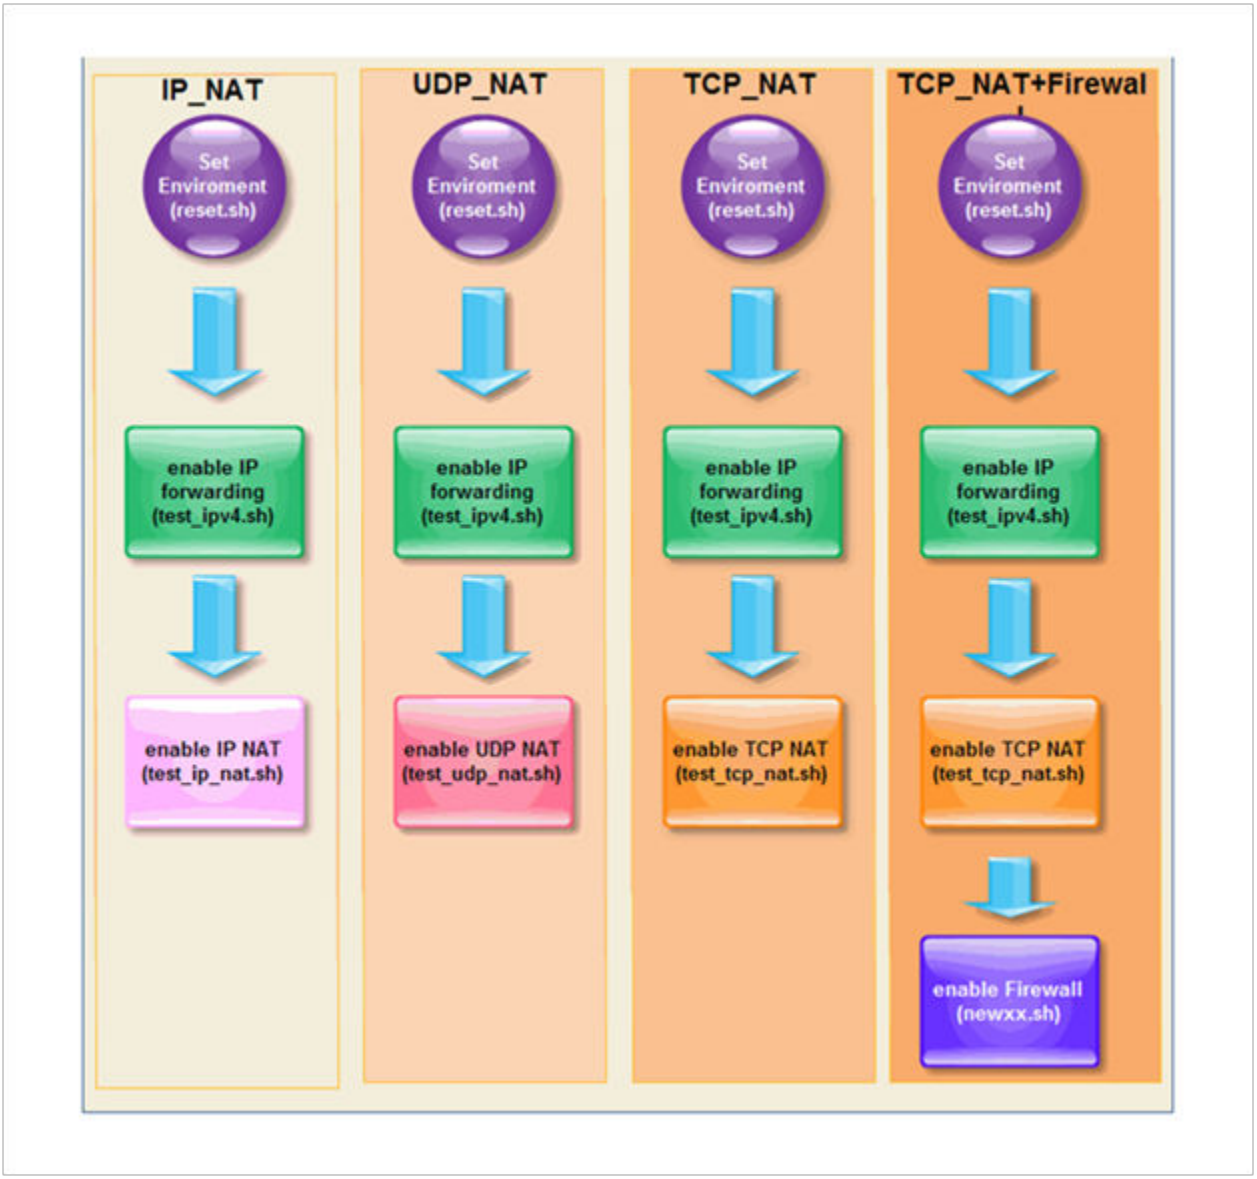


1. Connect two Ethernet cross cables between the target board and Smartbits Ethernet ports
2. Connect one Ethernet cross cable between a Windows PC and Smartbits management port
3. Run smartflow from Windows PC and connect to Smartbits, the Smartbits' IP is 10.193.20.212.
4. Set IP and MAC to adapt both Smartbits and the board.

LS1021ATWR NAT and Firewall Test Setup



LS1021ATWR Test Procedure



- Use reset.sh to set the environment which is included Source IP range, Fake IP range, income network device, output network device, then flush all rules in those tables and set the default policy for the tables.
- Use `test_ipv4.sh` to set QorIQ_SDK board IP address, do smartbit MAC and IP binding, and then enable IP Forwarding.
- Use `test_xxx_NAT.sh` to enable NAT translate.
- Use `newxxx.sh` to enable Firewall. `New1.sh` means 1 rule, new128 means 128 rules, new1024.sh means 1024 rules.

LS1021ATWR Test Tips

To improve performance, tune Rx and Tx interrupt coalescing values to reduce the interrupt rate. A more suitable (compared to the default values) set of parameters for the packet forwarding use case is:

- ```
  #ethtool -C eth0 rx-frames 32 rx-usecs 22 tx-frames 32 tx-usecs 22
  ```
- ```
  #ethtool -C eth1 rx-frames 32 rx-usecs 22 tx-frames 32 tx-usecs 22
  ```

These commands are used to tune the RX interrupt rate per RX/TX DMA channel. Also, it is recommended to set the Rx/ Tx interrupt affinities in such a way as to ensure Flow/CPU affinity, for improved performance.

12.2.7.4 Test Demos

Example Test Demo and scripts to setup the board to reproduce NAT and Firewall benchmark results.

LS1021ATWR Test Demos

Examples of test demo code are provided below.

1. IPV4 Forwarding + TCP NAT:

```

```

2. Test_ipv4.sh

```
ifconfig eth0 192.168.2.130 netmask 255.255.255.0 up
ifconfig eth1 192.168.1.131 netmask 255.255.255.0 up
ifconfig eth2 down
ifconfig eth3 down
ifconfig
arp -s 192.168.2.131 00:00:05:00:00:01
arp -s 192.168.1.130 00:00:06:00:00:01
echo 1 > /proc/sys/net/ipv4/ip_forward
cat /proc/sys/net/ipv4/ip_forward
```

3. Test_ip_nat.sh

```
#
# NAT (inbound)
#
# It seems we have problem to set this one up because NF conntrack is stateful
#
# NAT (outbound) using a range of IP and no ports
#
$IPT -t nat -A POSTROUTING -p ip -o $EXT_IFACE -m iprange --src-range \
```

```
 $SRC_IP_RANGE_2 -j SNAT --to-source $FAKE_SRC_IP_RANGE_2
#$IPT -t nat -A POSTROUTING -p ip -o $INT_IFACE -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p ip -o $EXT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p ip -o $INT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
# DO NOT edit beyond this line except for firewall operation
#. new32.sh
```

4. Test_UDP_NAT.sh

```
#
# NAT (inbound)
#
# It seems we have problem to set this one up because NF conntrack is stateful
#
# NAT (outbound) using a range of IP and no ports
#
$IPT -t nat -A POSTROUTING -p udp -o $EXT_IFACE -m iprange --src-range \
 $SRC_IP_RANGE_2 -j SNAT --to-source $FAKE_SRC_IP_RANGE_2:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p udp -o $INT_IFACE -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p udp -o $EXT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p udp -o $INT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
# DO NOT edit beyond this line except for firewall operation
#. new32.sh
```

5. Test_TCP_NAT.sh

```
#
# NAT (inbound)
#
# It seems we have problem to set this one up because NF conntrack is stateful
#
# NAT (outbound) using a range of IP and no ports
#
$IPT -t nat -A POSTROUTING -p tcp -o $EXT_IFACE -m iprange --src-range \
 $SRC_IP_RANGE_2 -j SNAT --to-source $FAKE_SRC_IP_RANGE_2:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p tcp -o $INT_IFACE -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p tcp -o $EXT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
#$IPT -t nat -A POSTROUTING -p tcp -o $INT_IFACE_2 -m iprange --src-range \
# $SRC_IP_RANGE_1 -j SNAT --to-source $FAKE_SRC_IP_RANGE_1:$PORT_RANGE
# DO NOT edit beyond this line except for firewall operation
#. new32.sh
```

6. New1.sh

```
$IPT -t filter -A FORWARD -i $INT_IFACE -d 255.128.0.0/9 -j REJECT
```

12.2.8 NAS - DPAA

How to setup a NAS - DPAA system on NXP QorIQ system, and how to measure its performance.

12.2.8.1 Benchmarking Objectives

The purpose of this guide is to show how to setup a NAS system on a NXP QorIQ DPAA system and how to measure its performance.

NOTE

P2040RDB /P2041RDB was used for the demo. Please refer to the board's manual for other DPAA boards.

12.2.8.2 Test Environment

NAS Client

The suggested NAS client is described in table 1. The client has high throughput performance to make sure the testbed would not limit the NAS performance. Any degradation to the suggested NAS client may lead to degradation of overall NAS performance.

Table 609. NAS client configuration

Item	Description
CPU	Minimum requires Intel® i5 CPU 750@2.67GHz
RAM	4G DDR3 RAM
Hard Drives	Western Digital® WD3000HLFS 10000RPM,Two drives configured in RAID 0 array, higher performance SSD a plus
Ethernet	Standalone Intel PRO/1000 PT Desktop Adapter (PCIE) for 1 Gbps bandwidth, or Intel PRO/1000 PT Quad Port Server Adapter for 4 Gbps bandwidth, 10 Gbps NICs are required for more than 8 HDD raid benchmarking
OS	Window® 7 (32bit) or Windows Vista®
Anti-virus software	off
Firewall software	off
Connection to NAS server	Direct connection through Ethernet cable without switches

NAS server

In this document, the NAS benchmark will be done on the P2041RDB and P2040RDB. A P2041RDB board can be configured to a P2040 board. For details, please refer to user manual of the board.

The SATA disk being used is Western Digital WD3000HLFS, 10000RPM. If lower speed SATA is used, it will impact the overall NAS performance.

P2041/P2040 has only 2 onboard SATA connector, which is not enough to compose RAID5 array. Therefore, 2 ports PCIe to SATA adaptor will be used for RAID5 tests.

See Table 2 for details.

Table 610. NAS server configuration

Item	Description
Silicon and board	P2041RDB P2040RDB

Table continues on the next page...

Table 610. NAS server configuration (continued)

Item	Description
RAM	4G DDR3 RAM
Hard Drives	Western Digital WD3000HLFS 10000 RPM, higher performance SSD a plus Single drive or four drives configured in RAID 5 array, for others RAID6/0/10 NAS, please refer to NXP RAID benchmark guide
Ethernet	Onboard dTSECs or TGECs
PCIe-SATA adaptor	At least 2 x Silicon Image 3132, 2 x LSI-9221 cards, a plus
MTU setting	MTU=1500, 9014
OS	Linux BSP, SDK 2.0 kernel version 4.1.8 or later

Measurement

- File copy under Windows7
- The tests are done using the robocopy command built into Windows 7 (and available as a download as part of the free Windows Server® 2003 Resource Kit Tools).
- The benchmarks consist of Write and Read transfers of a single file which size is 8 GB (double size of the NAS server memory).
- A result of (XXX) MB/s means (YYYYYYYYY) Bytes/1024/1024 instead of (YYYYYYYYY) Bytes/1000/1000.
- The CPU utilization should be recorded when the throughput is being recorded.

Important tips for the best performance

U-boot part

- Make sure 2 PCIe slots enable and configured as PCIe x 4 to boost RAID5 and SATA performance

Linux kernel part

1. Use the corenet32_smp_defconfig to configure your kernel and make sure to enable:
   - FSL_DPAA_ETH_OPTIMIZE_FOR_TERM
   - FSL_DPAA_ETH_SG_SUPPORT
   - FSL_FM_RX_EXTRA_HEADROOM=0
   - FMAN_P3040_P4080_P5020=[y]
   - EXT4_FS
2. Make sure to disable:
   - FSL_DPAA_OFFLINE_PORTS
   - FSL_DPAA_1588
   - NETFILTER

Others

1. Enable NIC IPv4 checksum offload in both NAS server and NAS client
2. Enable NIC TCP RX/TX checksum offload in both NAS server and NAS client
3. Ensure PCD effective in NAS server, and disable unused network interface in the PCD config file
4. Ensure every NIC works at proper 1 Gbps or 10 Gbps Full Duplex mode as expected

5. While benchmarking performance in multi-client mode, ensure every file which will be copied will deploy to different NAS client disks.
6. Use SSD to instead of normal machine disk if possible
7. The performance of local SATA/RAID5 should be guaranteed. To enable the SEC to offload the XOR for RAID5, refer to the local SATA/RAID5 benchmark guide.
8. Use multi-client mode to avoid a network interface bottle-neck. To calculate of number of networking interfaces, use the following formula:

   (Maximum throughput of local SATA/RAID5/RAID6 reading) / (Line speed of every networking interface) = Number of networking interfaces

   For example:

   (750 MB/s) / (110 MB/s) = 6.8 means that 7 network interfaces of 1 Gbps and 7 clients are needed or one 10 Gbps networking interface is needed.

12.2.8.3 Test Procedure

This section describes the test procedure for various configurations of a DPAA NAS

12.2.8.3.1 Single-core single-disk single-client

Hardware setup

Connect a single disk to a Silicon Image PCIe-SATA adaptor (Figure 3.1.1) on the P2041RDB board then benchmark the NAS performance of single-disk/single-client.

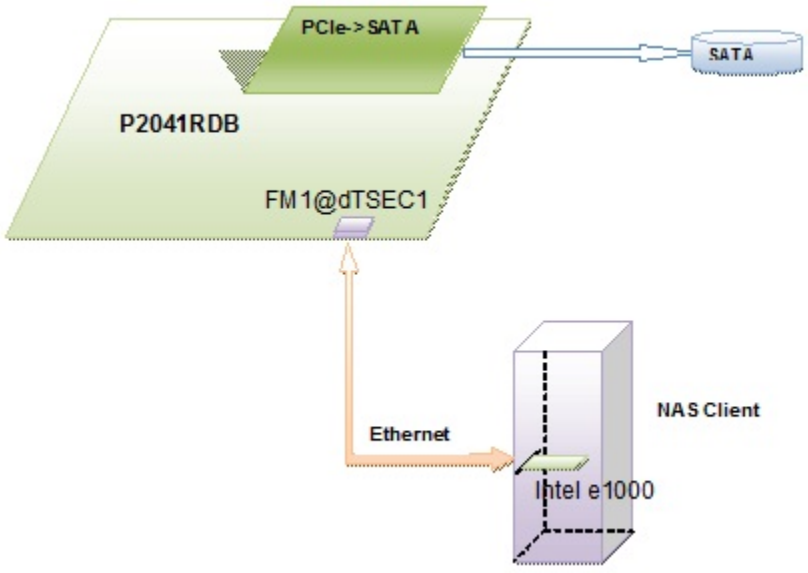

Figure 382. Figure 3.1.1

Test procedures

Please follow the below steps to have single-disk/single-client NAS performance test:

1. Power on the P2041 board, in u-boot, use the following command to disable other 3 cores and only enable 1 core:
   - >cpu disable 3
   - >cpu disable 2

- >cpu disable 1

2. Continue to boot up the P2041 board into Linux. Type “root” to enter the Linux command line.
3. Setup shared folder on P2041 board with below commands. Suppose the shared folder is /smbshare:
   - a)mkfs.ext2 /dev/sda1
   - b)mount /dev/sda1 /smbshare
   - c)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - d)ifconfig fm1-gb0 192.168.1.100
   - e)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - f)ethtool –K fm1-gb0 gro on gso on sg on

   If you want to use EXT4 file system, change above command a) b) to:

   - a’) mkfs.ext4 /dev/sda1
   - b’) mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/sda1 /smbshare
4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On NAS client side, map the shared folder /smbshare as a windows drive, e.g, drive z. Please refer to the below steps for details, then you will get a new drive as figure 3.1.2.
   - a)Connect the NAS client and the board directly by a crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx
   - c)Open a command prompt window on NAS client and input the following command to map the shared folder as a windows drive:
     - Net use Z: \\192.168.1.100\public

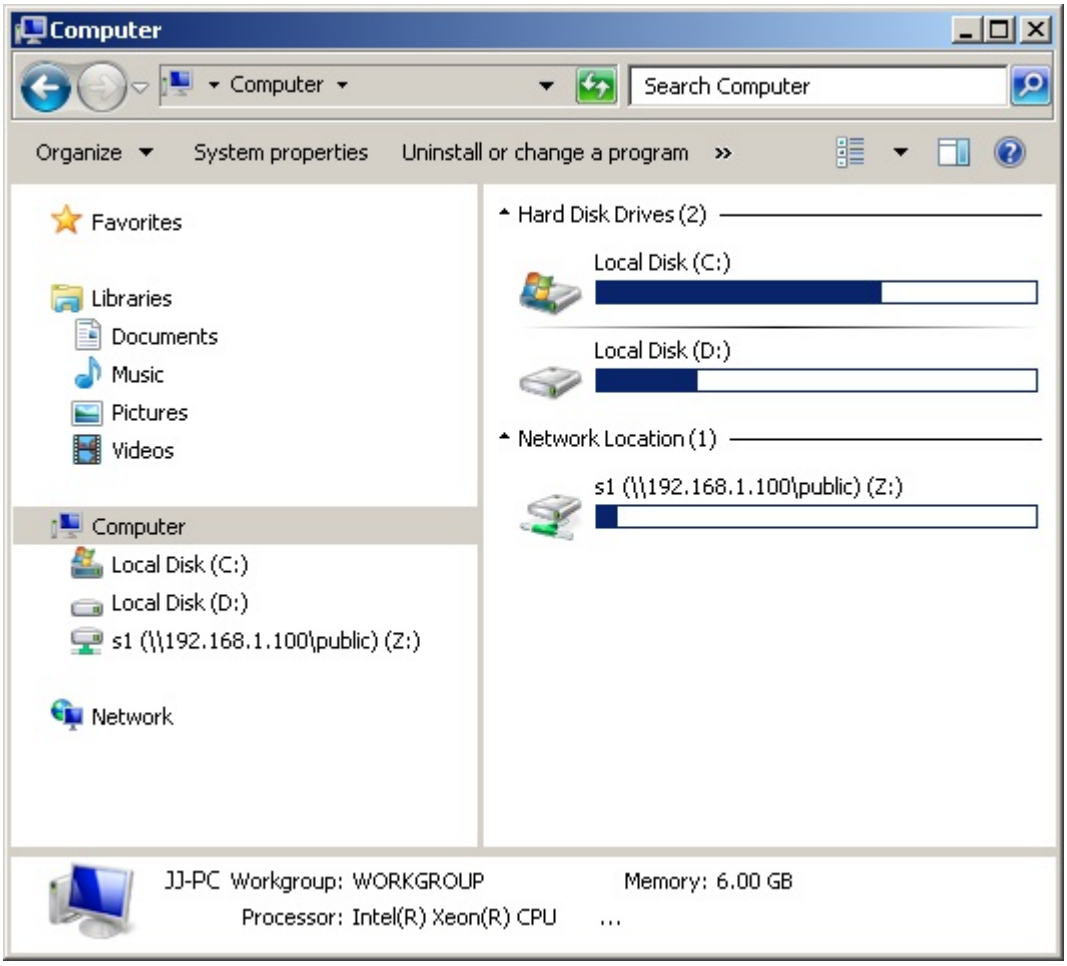

Figure 383. Figure 3.1.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.
   - a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel-> System and Security-> System-> Device Manager-> Intel(R) PRO/1000 PT Desktop Adapter and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.1.3.
   - b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
     - # ifconfig fm1-gb0 mtu 9014

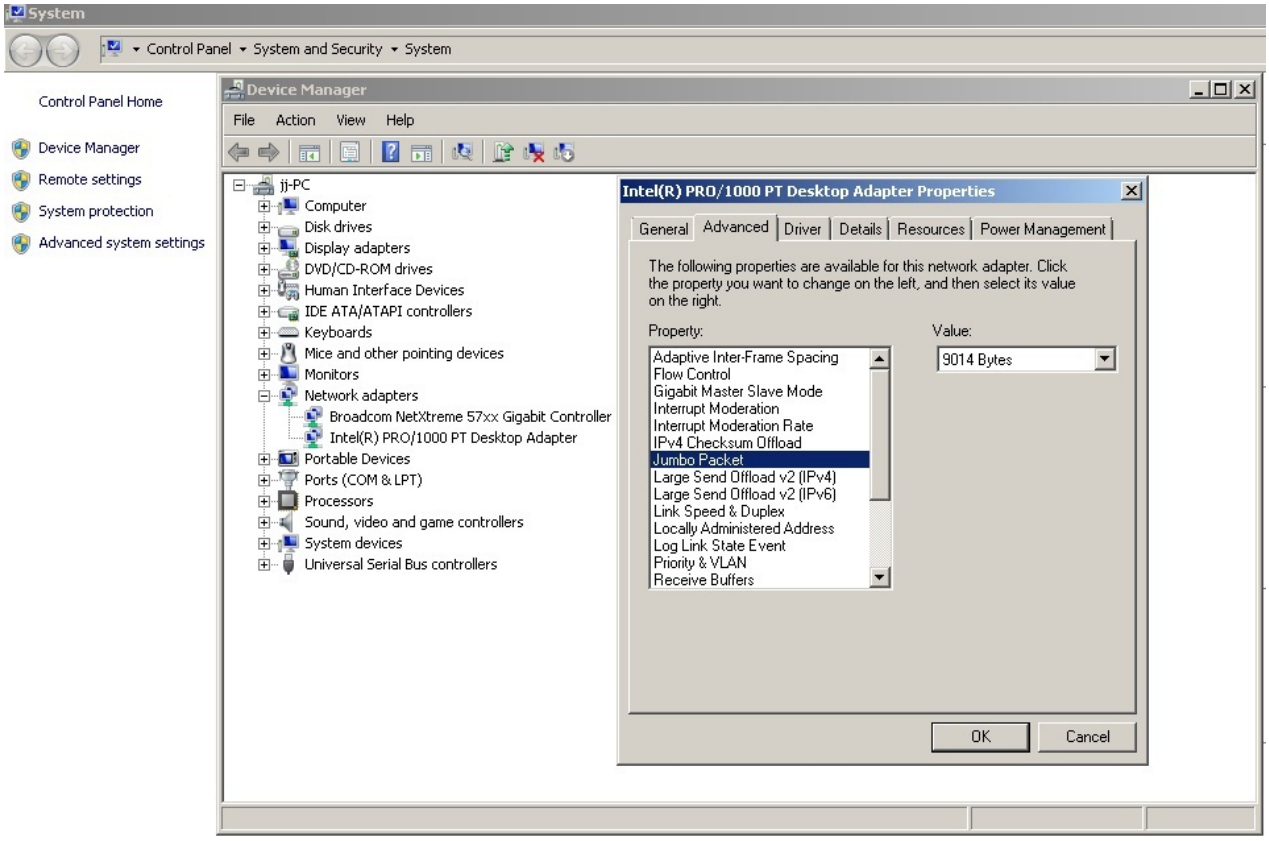

Figure 384. Figure 3.1.3

7. Generate a dummy file with 2GB with the following command at NAS client side:
   - prompt> fsutil file createnew 2G.001 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance: Prompt> robocopy . z:\ 2G.001 /NP /NS /COPY:D
   - To test reading performance: Prompt> robocopy z:\ . 2G.001 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.
   - b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
   - c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.1.4 shows:

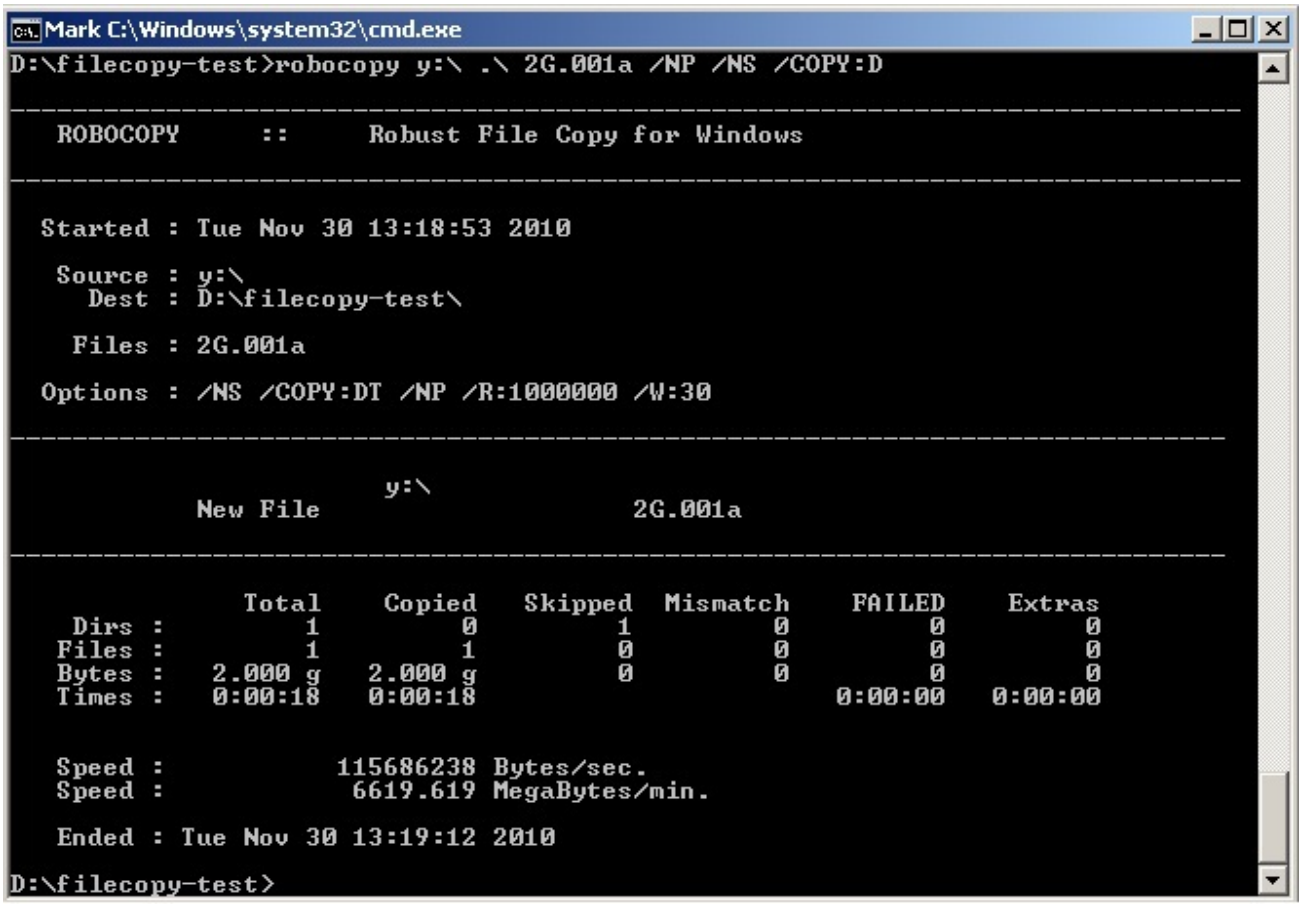

Figure 385. Figure 3.1.4

Here is the example robocopy result of reading 2G file. The number is 6619.619 MegaBytes/min. It means the reading speed is about 110MB/s that can be computed by 6619.619/60.

12.2.8.3.2 Single-core RAID5 single-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors, as shown in figure 3.2.1.

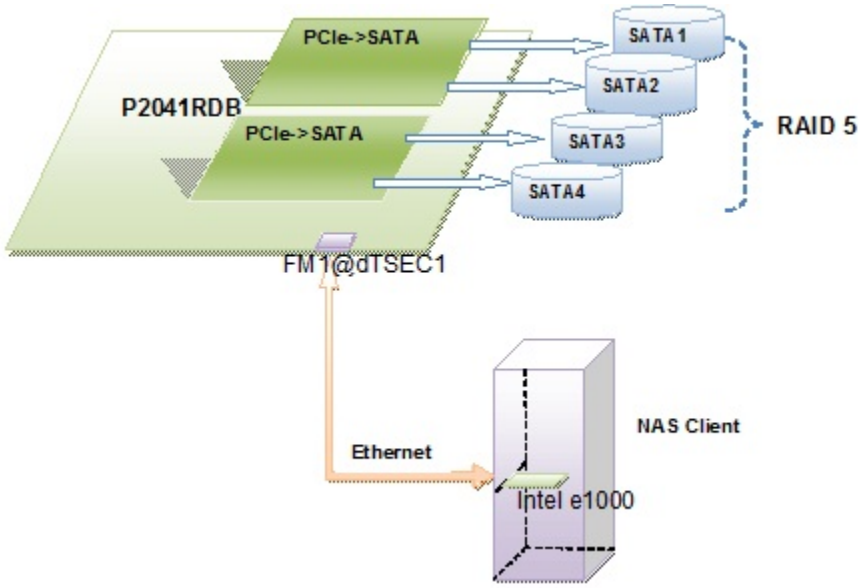

Figure 386. Figure 3.2.1

Test procedures

Please follow the below steps to have RAID5/single-client NAS performance test:

1. Power on the P2041 board, in u-boot, use the following command to disable other 3 cores and only enable 1 core:
   - >cpu disable 3
   - >cpu disable 2
   - >cpu disable 1
2. Continue to boot up the P2041 board into Linux. Type "root" to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - e)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - f)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - h)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - i)ifconfig fm1-gb0 192.168.1.100
   - j)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - k)ethtool –K fm1-gb0 gro on gso on sg on

   If you want to use EXT4 file system, change above command b) c) to:

   - b') mkfs.ext4 /dev/md0

- c') mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On NAS client side, map the shared folder /smbshare as a windows drive, e.g, drive z. Please refer to the below steps for details, then you will get a new drive as figure 3.2.2.

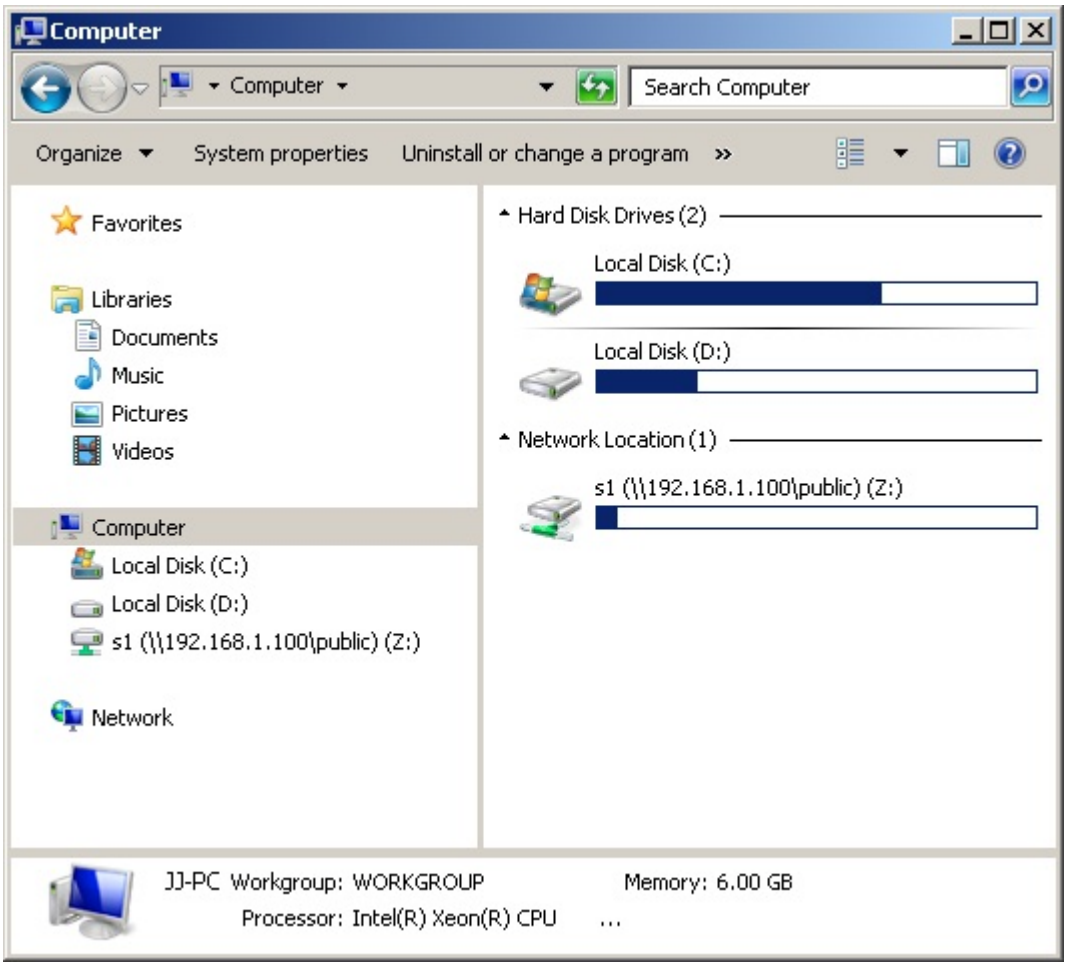

Figure 387. Figure 3.2.2

- a)Connect the NAS client and the board directly by a crossover network cable.
- b)Set up the NAS client IP to 192.168.1.xxx
- c)Open a command prompt window on NAS client and input the following command to map the shared folder as a windows drive:
  - Net use Z: \\192.168.1.100\public

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.

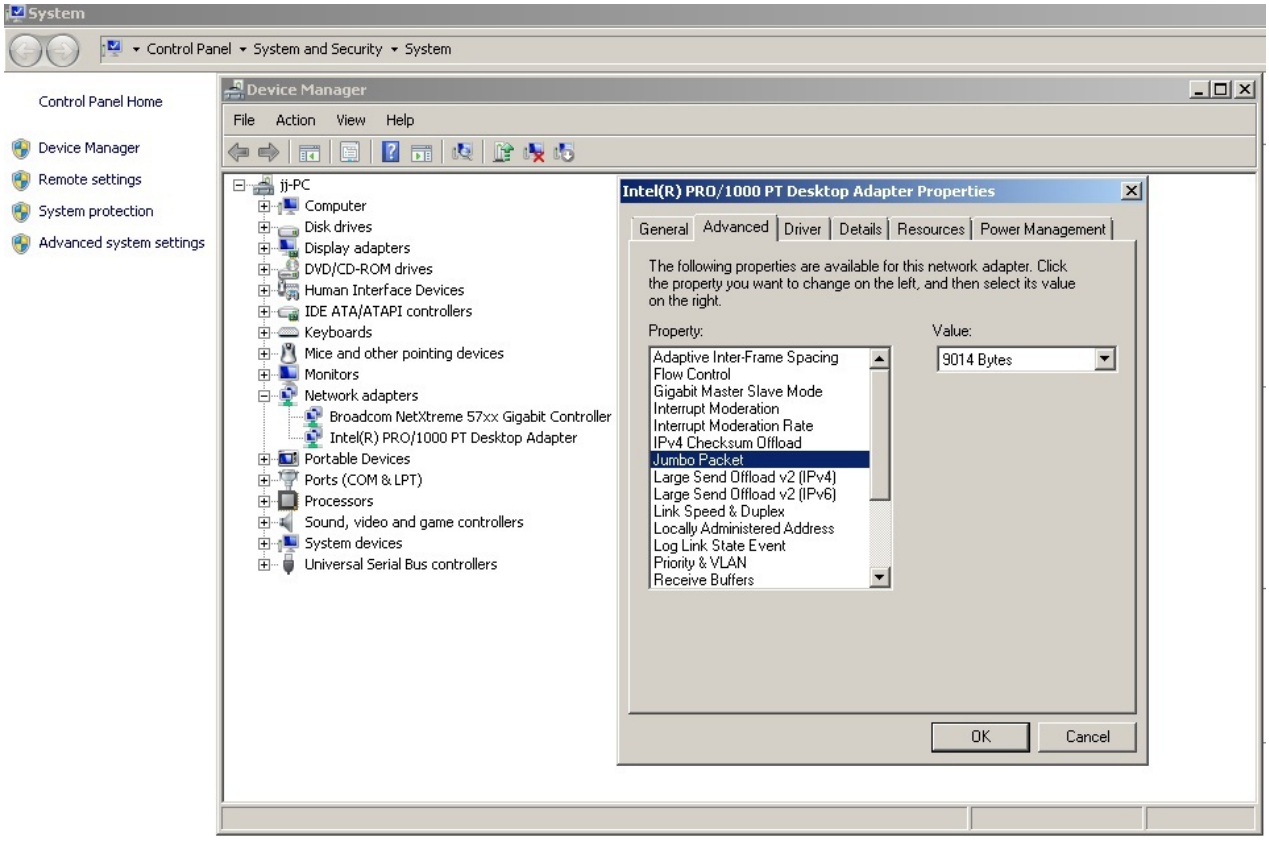

Figure 388. Figure 3.2.3

- a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel-> System and Security-> System-> Device Manager-> Intel(R) PRO/1000 PT Desktop Adapter and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.2.3.
- b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
  - # ifconfig fm1-gb0 mtu 9014

7. Generate a dummy file with 2GB with the following command at NAS client side:
   - prompt> fsutil file createnew 2G.001 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance: Prompt> robocopy . z:\ 2G.001 /NP /NS /COPY:D
   - To test reading performance: Prompt> robocopy z:\ . 2G.001 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.
   - b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
   - c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.2.4 shows:

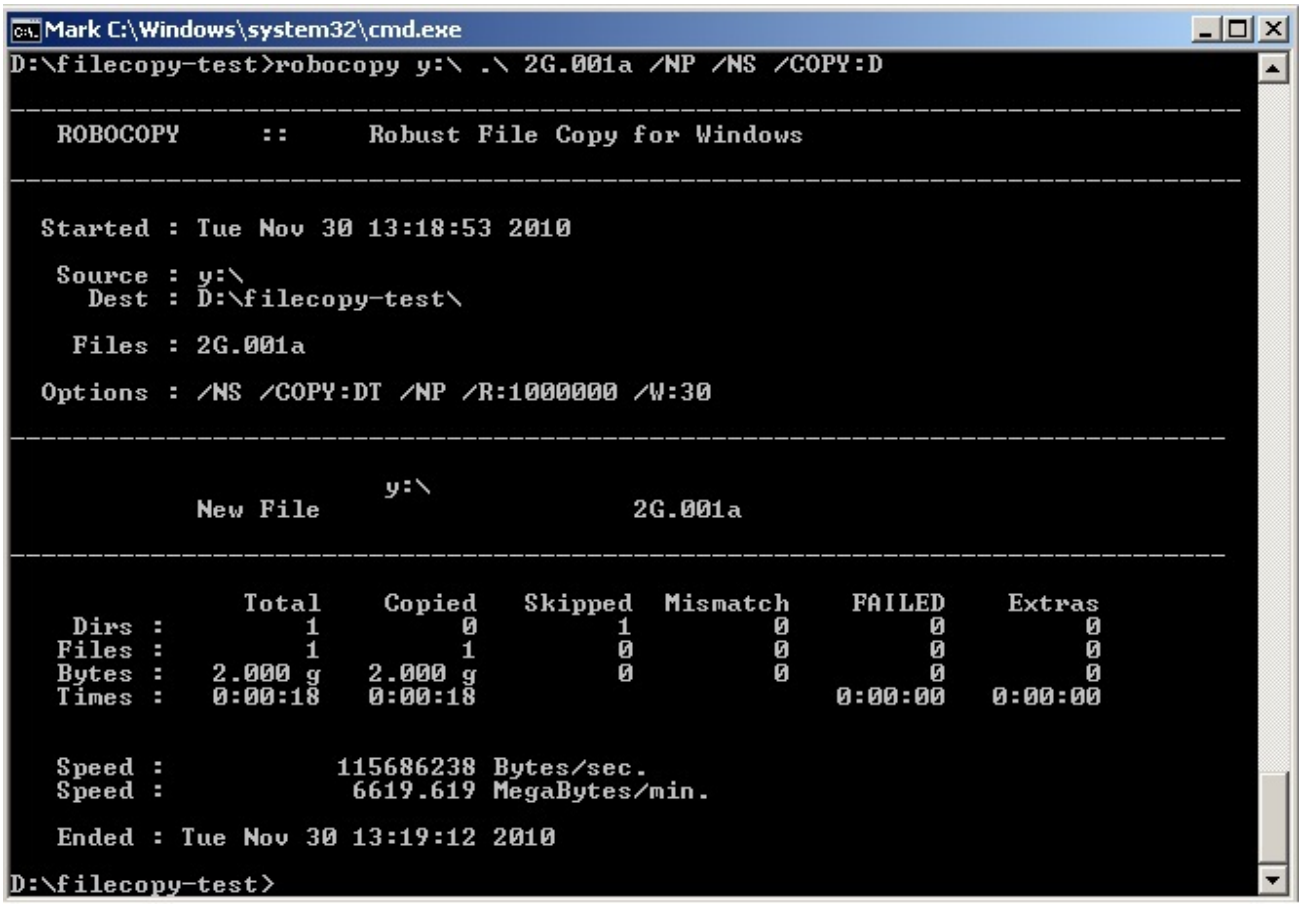

Figure 389. Figure 3.2.4

Here is the example robocopy result of reading 2G file. The number is 6619.619 MegaBytes/min. It means the reading speed is about 110MB/s that can be computed by 6619.619/60.

12.2.8.3.3 Two-core RAID5 single-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors, as shown in figure 3.3.1.

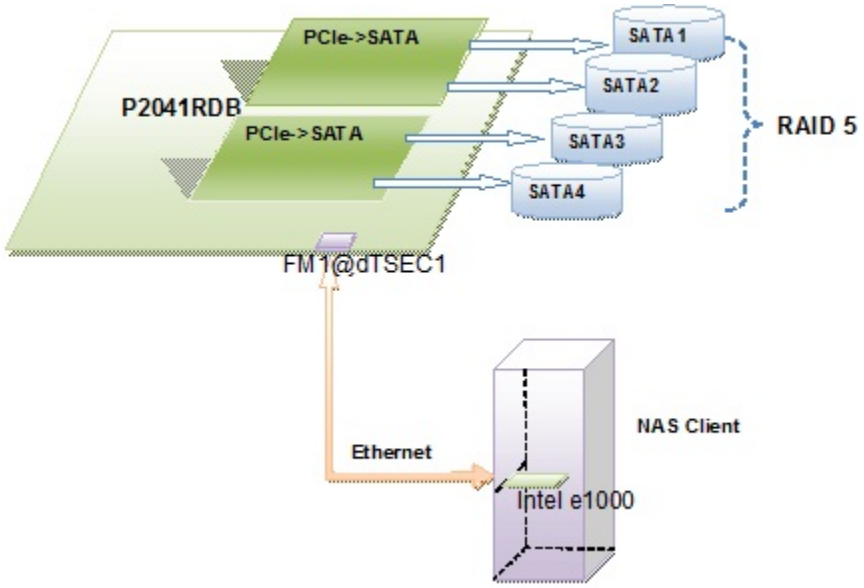

Figure 390. Figure 3.1.1

Test procedures

Please follow the below steps to have RAID5/single-client NAS performance test:

1. Power on the P2041 board, in u-boot, use the following command to disable other 3 cores and only enable 2 cpu core:
   - >cpu disable 3
   - >cpu disable 2
2. Continue to boot up the P2041 board into Linux. Type “root” to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - e)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - f)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - h)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - i)ifconfig fm1-gb0 192.168.1.100
   - j)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - k)ethtool –K fm1-gb0 gro on gso on sg on

   If you want to use EXT4 file system, change above command b) c) to:

   - b’) mkfs.ext4 /dev/md0
   - c’) mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On NAS client side, map the shared folder /smbshare as a windows drive, e.g, drive z. Please refer to the below steps for details, then you will get a new drive as figure 3.3.2.
   - a)Connect the NAS client and the board directly by a crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx
   - c)Open a command prompt window on NAS client and input the following command to map the shared folder as a windows drive:
     - Net use Z: \\192.168.1.100\public

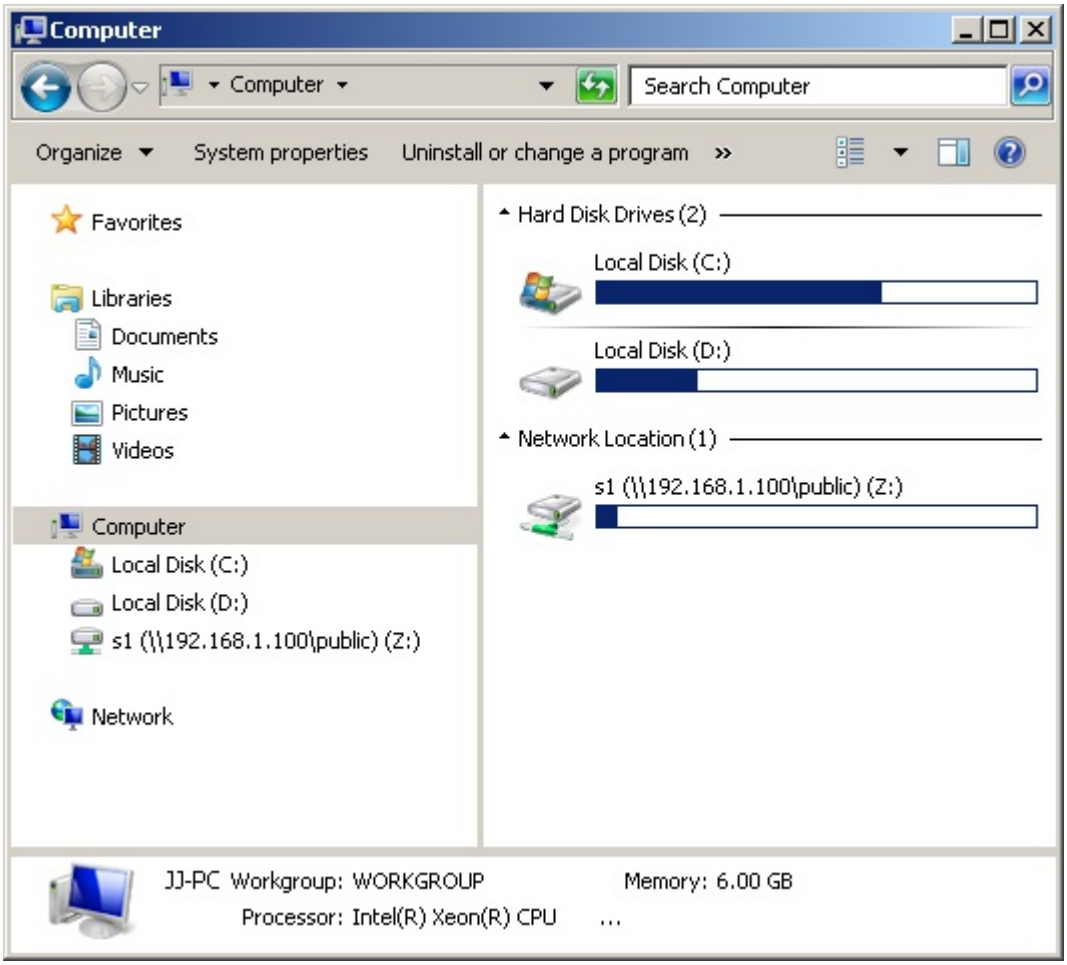

Figure 391. Figure 3.3.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.

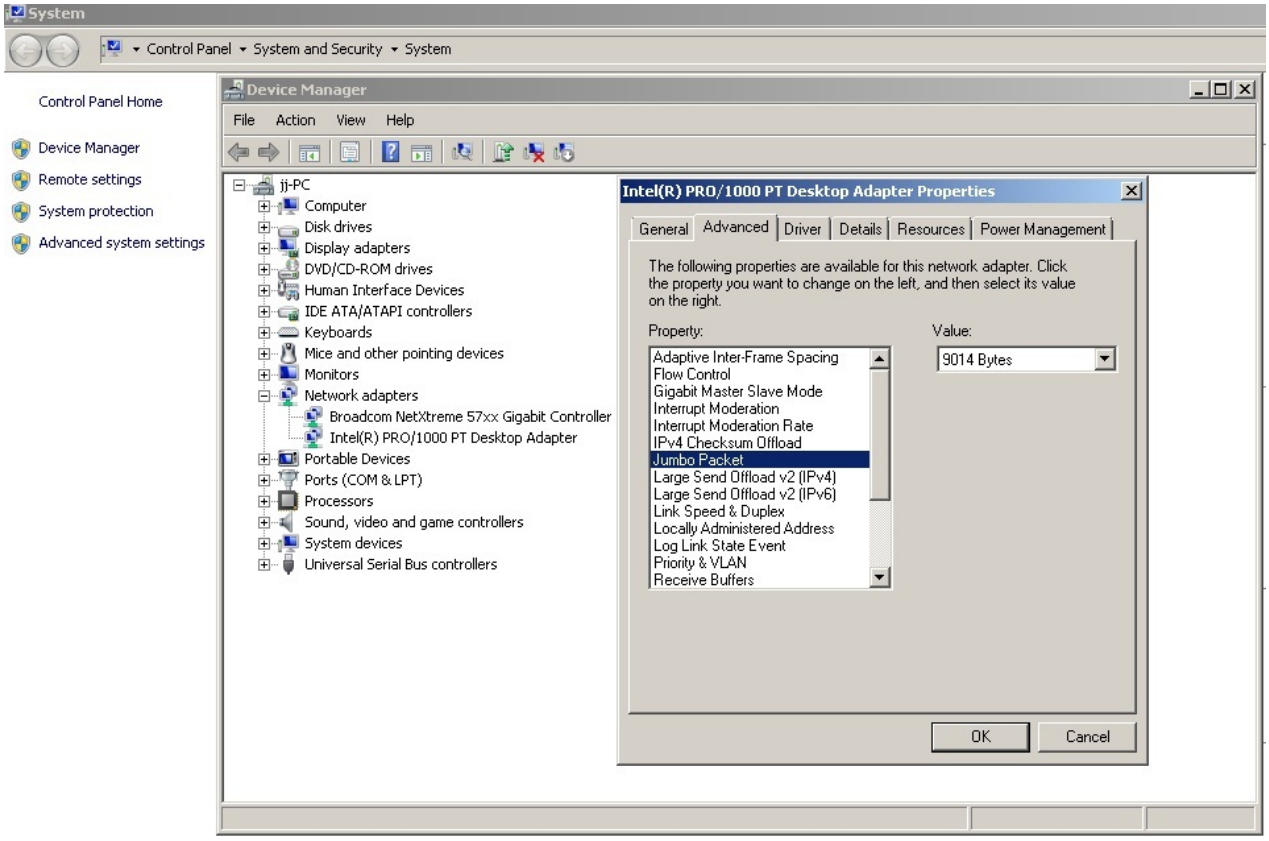

Figure 392. Figure 3.3.3

- a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel-> System and Security-> System-> Device Manager-> Intel(R) PRO/1000 PT Desktop Adapter and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.3.3.
- b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
  - # ifconfig fm1-gb0 mtu 9014

7. Generate a dummy file with 2GB with the following command at NAS client side:
   - prompt> fsutil file createnew 2G.001 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance: Prompt> robocopy . z:\ 2G.001 /NP /NS /COPY:D
   - To test reading performance: Prompt> robocopy z:\ . 2G.001 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.
   - b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
   - c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.3.4 shows:

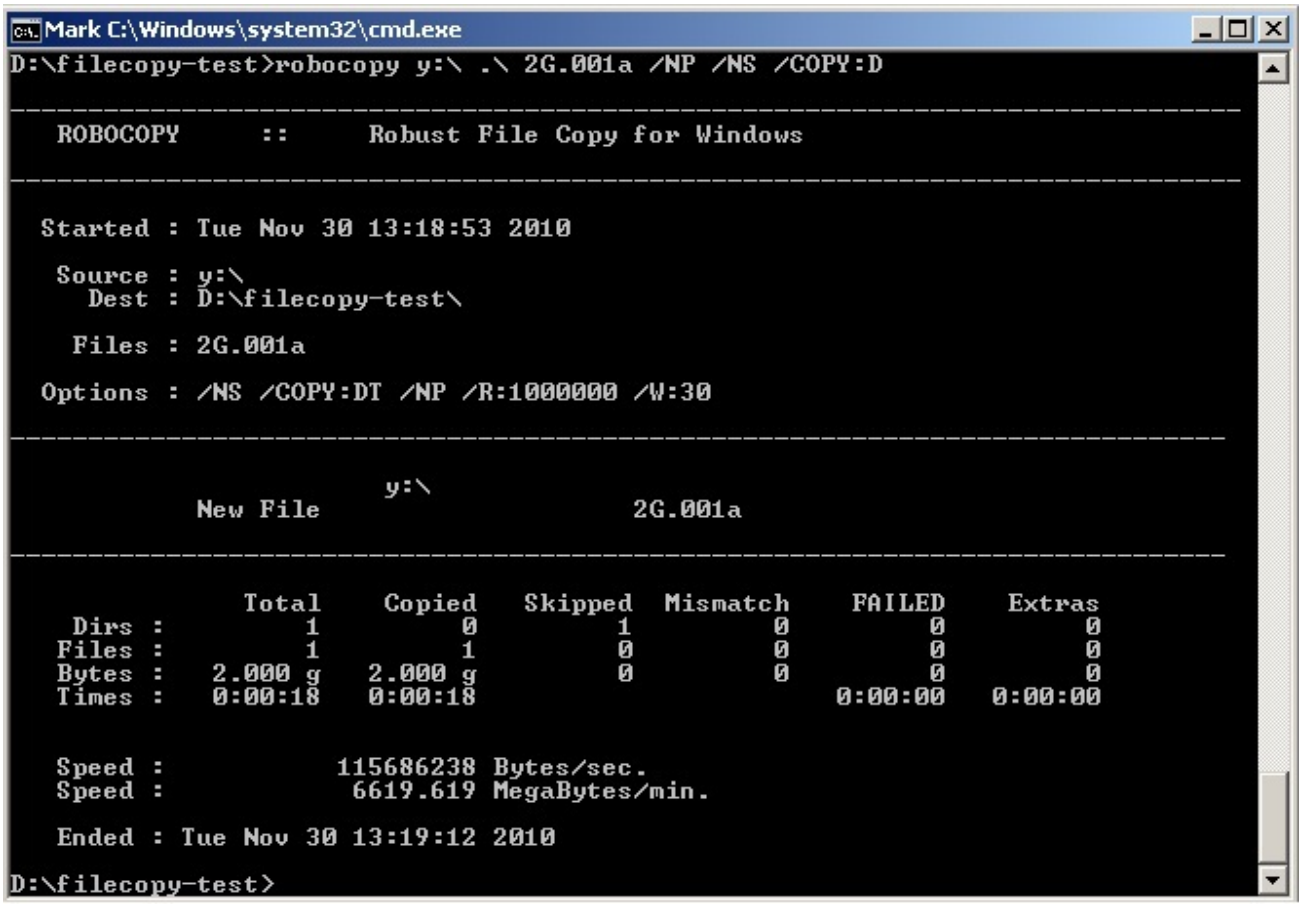

Figure 393. Figure 3.3.4

Here is the example robocopy result of reading 2G file. The number is 6619.619 MegaBytes/min. It means the reading speed is about 110MB/s that can be computed by 6619.619/60.

12.2.8.3.4 Two-core RAID5 two-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors. The network connections are shown below:

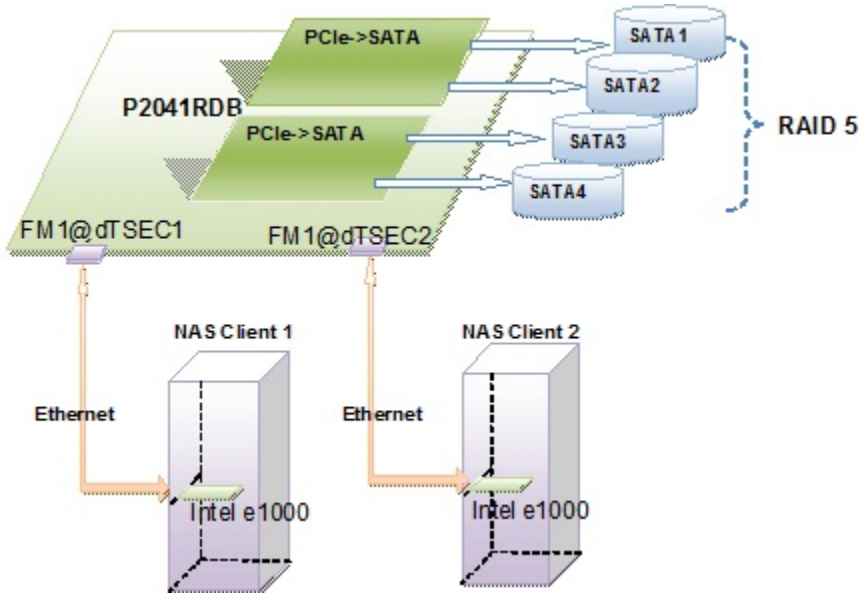

Figure 394. Method 1 is as figure 3.4.1:

Test procedures

Please follow the below steps to have RAID5/two-client NAS performance test:

1. Power on the P2041 board, in u-boot, use the following command to disable other 3 cores and only enable 2 cpu core:
   - >cpu disable 3
   - >cpu disable 2
2. Continue to boot up the P2041 board into Linux. Type “root” to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)mkdir /smbshare/{s1,s2} -p
   - e)chmod 777 /smbshare
   - f)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - h)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - i)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - j)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - k)ifconfig fm1-gb0 192.168.1.100/24
   - l)ifconfig fm1-gb1 192.168.2.100/23
   - m)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - n)ethtool –K fm1-gb0 gro on gso on sg on

- o)ethtool –K fm1-gb1 gro on gso on sg on

If you want to use EXT4 file system, change above command b) c) to:

- b') mkfs.ext4 /dev/md0
- c') mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On each NAS client side, map the shared folder /smbshare as 2 windows drives, e.g, drive z. Please refer to the below steps for details, then you will get 2 new drive as figure 3.4.2.
   - a)Connect the NAS client and the board directly by 2 crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx/24 and 192.168.2.yyy/23
   - c)Open a command prompt window on NAS client and input the following command to map the shared folders as 2 windows drives:
     - Net use Z: \\192.168.1.100\public\s1
     - Net use Y: \\192.168.2.100\public\s2

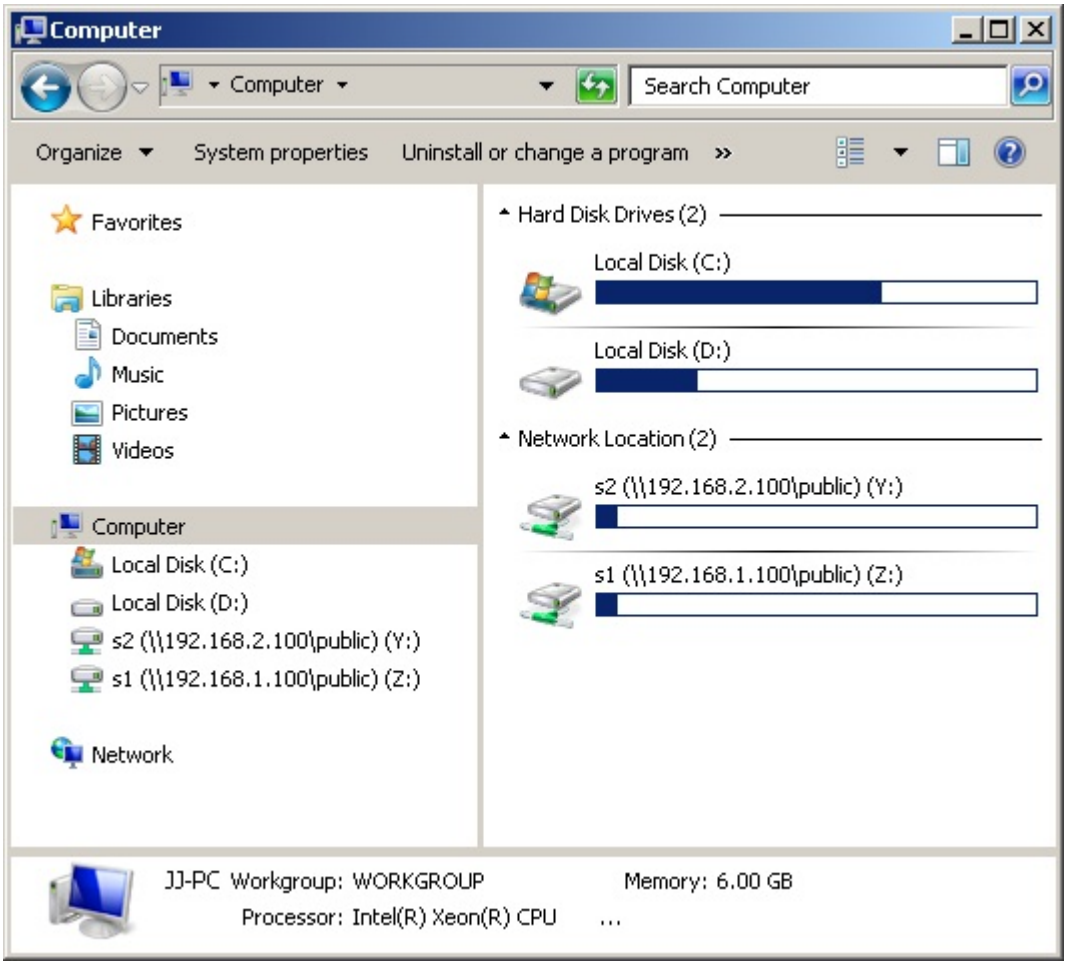

Figure 395. Figure 3.4.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.

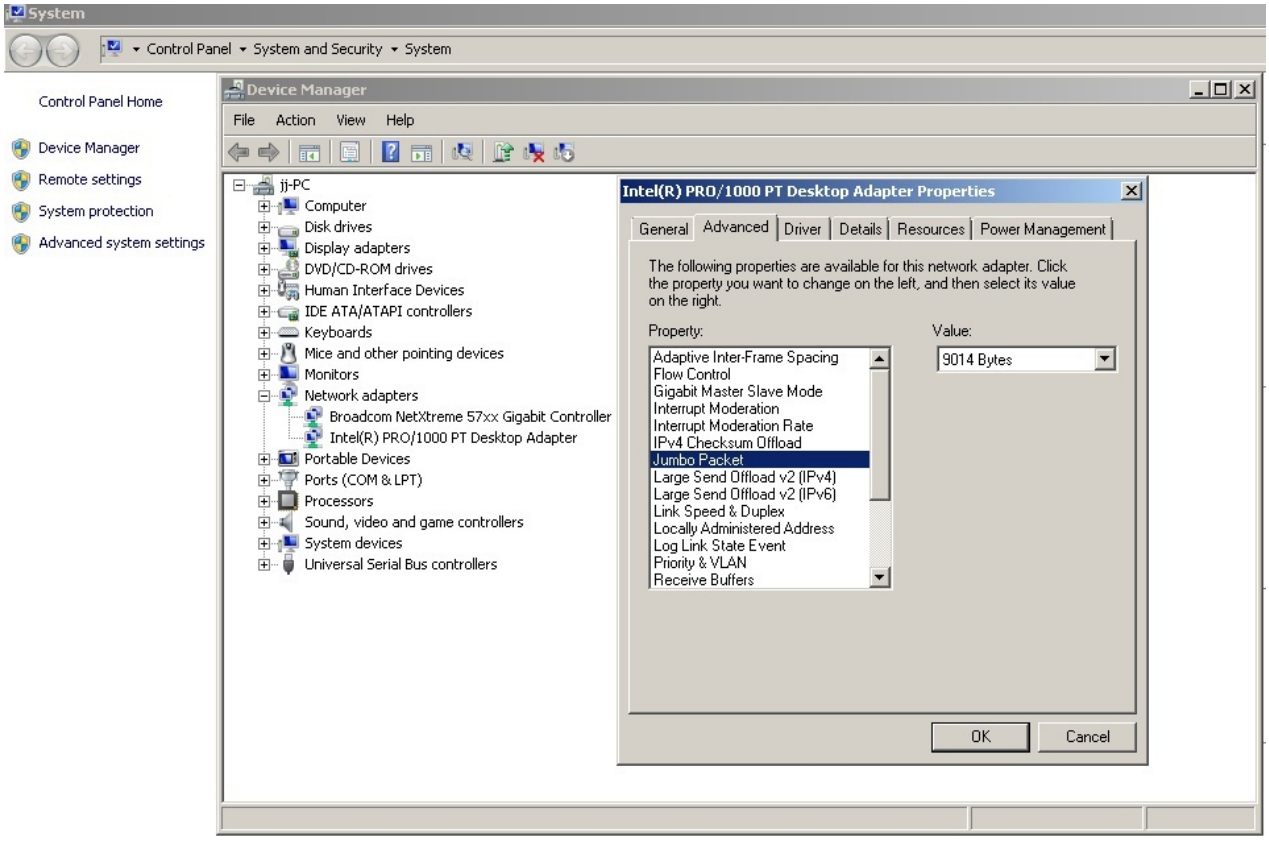

Figure 396. Figure 3.4.3

- a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel->System and Security->System->Device Manager->" Intel(R) PRO/1000 PT Quad Port Server Adapter " and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.4.3.
- b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
  - # ifconfig fm1-gb0 mtu 9014
  - # ifconfig fm1-gb1 mtu 9014

7. Generate 2 dummy files with 2GB with the following command in two NAS client side command prompt windows, it's better put the two files in different hard disk:
   - prompt> fsutil file createnew 2G.001 2147483648
   - prompt> fsutil file createnew 2G.002 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy C:\ Z:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy D:\ Y:\ 2G.002 /NP /NS /COPY:D
   - To test reading performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy Z:\ C:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy Y:\ D:\ 2G.002 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.

- b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
- c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.4.4 shows:

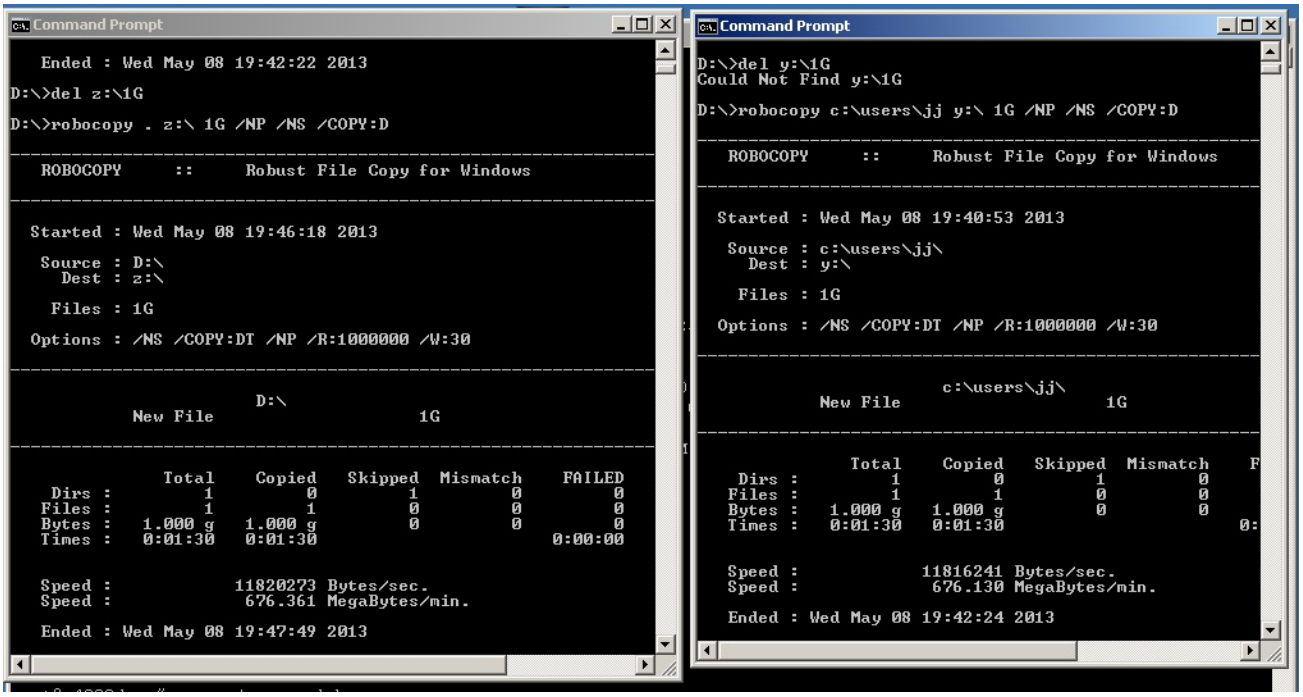

Figure 397. Figure 3.4.4

Here are the example robocopy results of reading 1G file in 2 command prompt windows of the NAS client. The numbers are 676.361 MegaBytes/min and 676.130 MegaBytes/min. It means the 1st client reading speed is about 11MB/s that can be computed by (676.361 MegaBytes/min) / (60second/min) and the 2nd client reading speed is about 11MB/s that can be computed by (676.130 MegaBytes/min) / (60 second/min). You should calculate the last result by adding two single client result:

The last result = $\sum_{i=1}^{2} result\ \ in\ \ client_i$ = 11MB/s +11MB/s =22MB/s

12.2.8.3.5 Four-core RAID5 single-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors, as shown in figure 3.5.1.

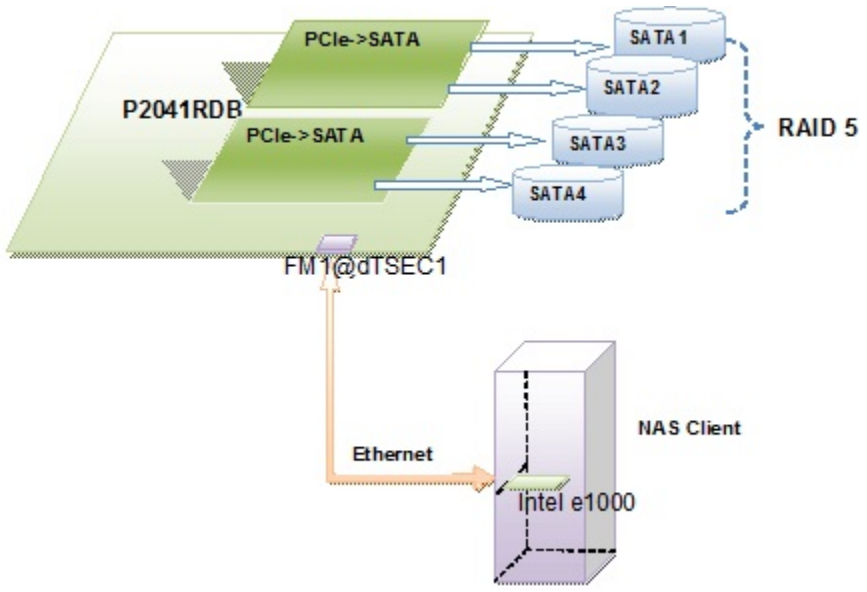

Figure 398. Figure 3.5.1

Test procedures

Please follow the below steps to have Four-core RAID5/single-client NAS performance test:

1. 1.Power on the P2041 board and make sure 4 cores enabled.
2. Continue to boot up the P2041 board into Linux. Type "root" to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - e)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - f)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - h)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - i)ifconfig fm1-gb0 192.168.1.100
   - j)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - k)ethtool –K fm1-gb0 gro on gso on sg on

   If you want to use EXT4 file system, change above command b) c) to:

   - b') mkfs.ext4 /dev/md0
   - c') mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare
4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf

5. 5.On NAS client side, map the shared folder /smbshare as a windows drive, e.g, drive z. Please refer to the below steps for details, then you will get a new drive as figure 3.5.2.
   - a)Connect the NAS client and the board directly by a crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx
   - c)Open a command prompt window on NAS client and input the following command to map the shared folder as a windows drive:
     - Net use Z: \\192.168.1.100\public

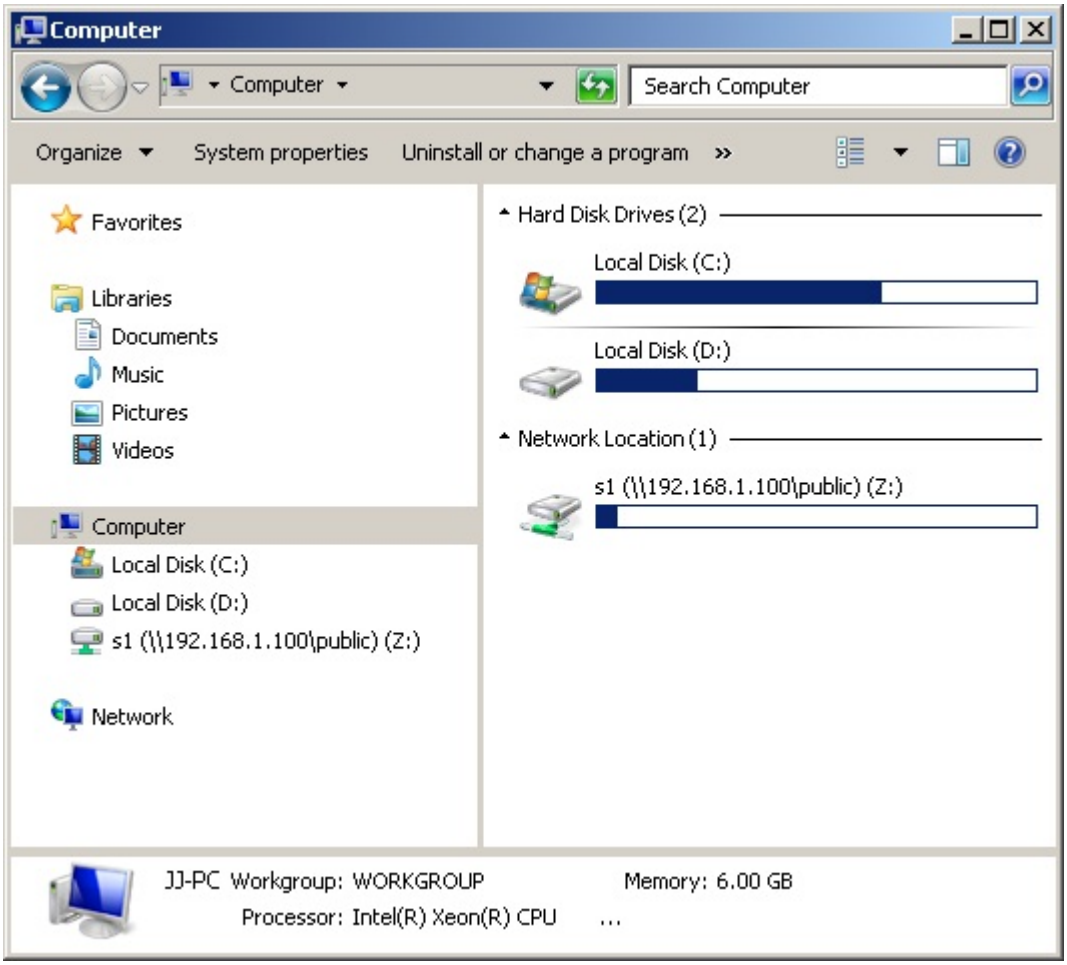

Figure 399. Figure 3.5.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.

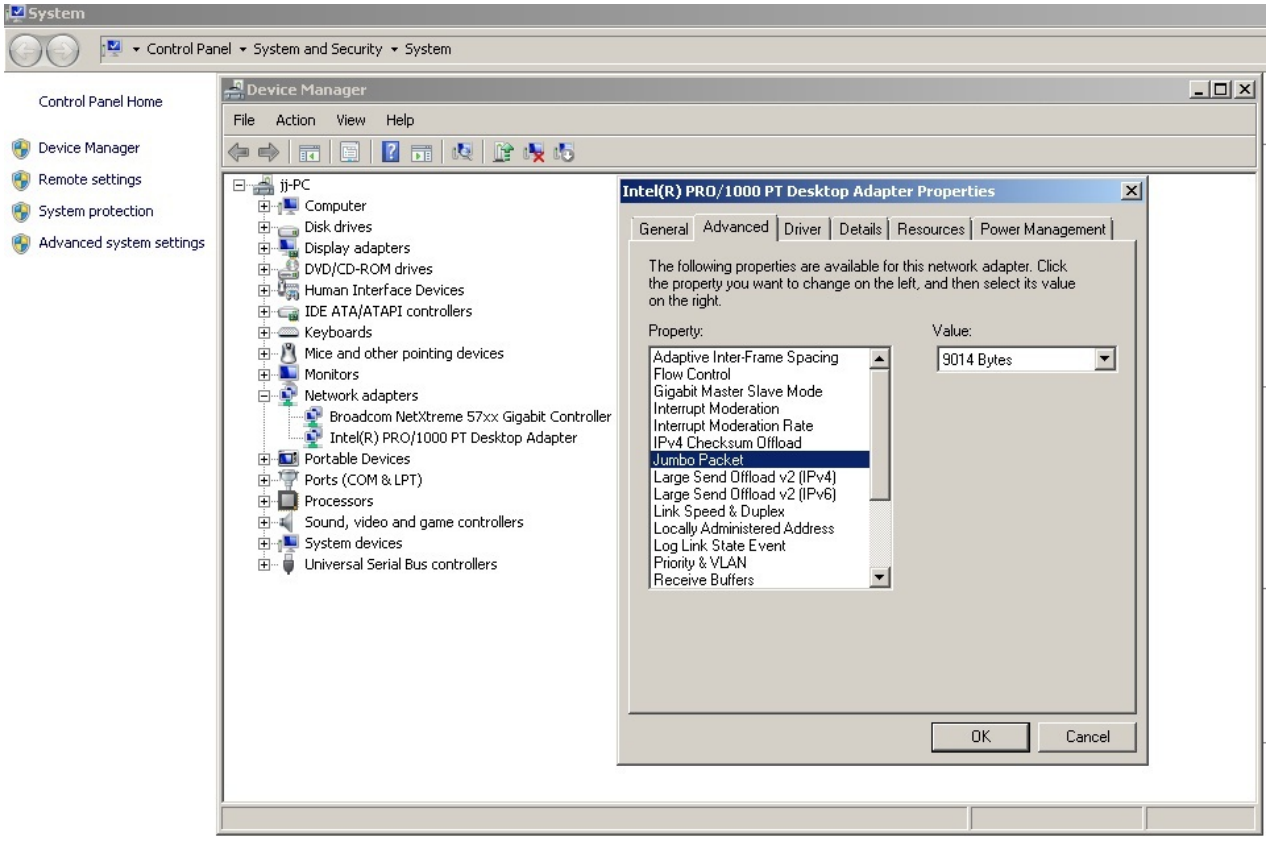

Figure 400. Figure 3.5.3

- a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel->System and Security->System->Device Manager->Intel(R) PRO/1000 PT Desktop Adapter and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.5.3.
- b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
  - # ifconfig fm1-gb0 mtu 9014

7. Generate a dummy file with 2GB with the following command at NAS client side:
   - prompt> fsutil file createnew 2G.001 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance: Prompt> robocopy . z:\ 2G.001 /NP /NS /COPY:D
   - To test reading performance: Prompt> robocopy z:\ . 2G.001 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.
   - b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
   - c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.5.4 shows:

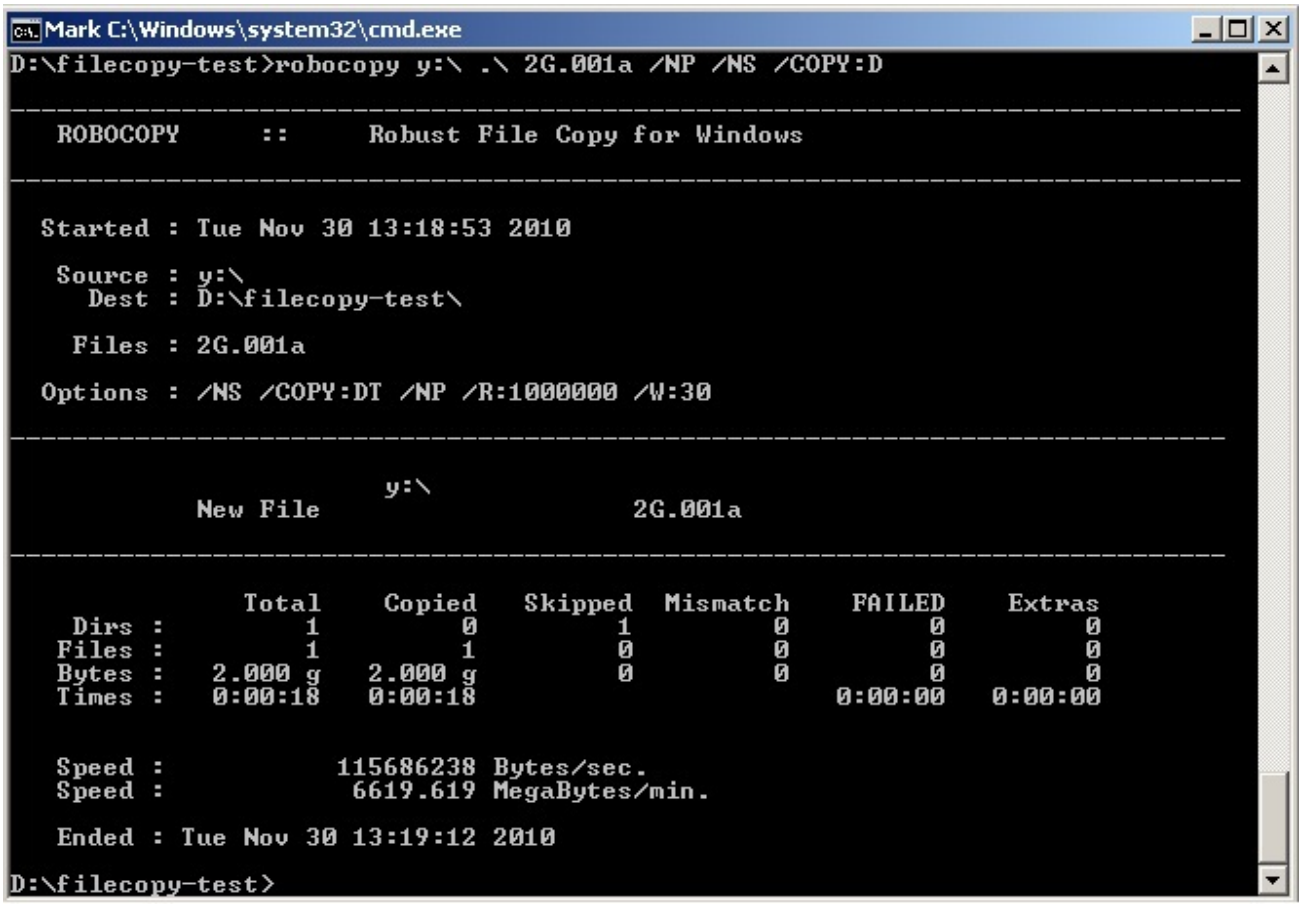

Figure 401. Figure 3.5.4

Here is the example robocopy result of reading 2G file. The number is 6619.619 MegaBytes/min. It means the reading speed is about 110MB/s that can be computed by 6619.619/60.

12.2.8.3.6 Four-core RAID5 two-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors. The network connection is shown as below

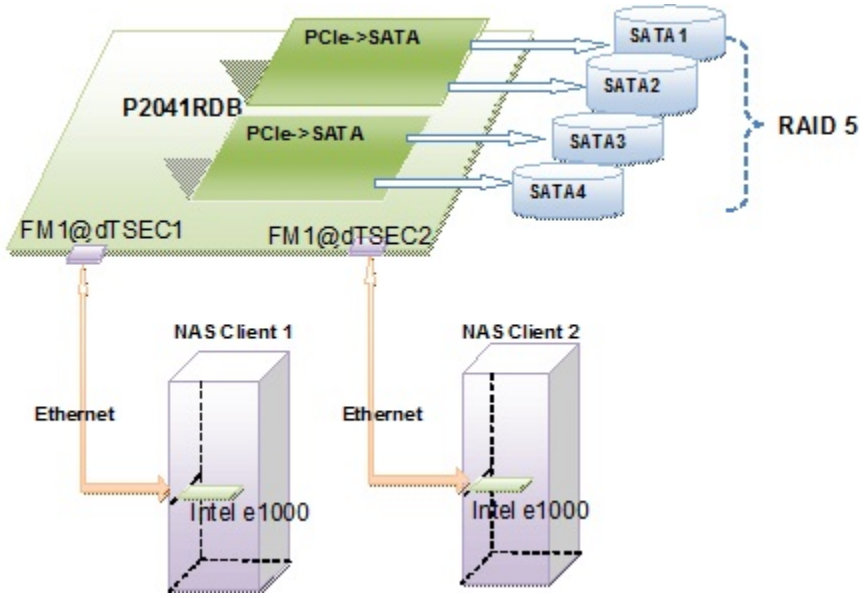

Figure 402. Method 1 is as figure 3.6.1:

Test procedures

Please follow the below steps to have RAID5/two-client NAS performance test:

1. Power on the P2041 board and make sure 4 cores enabled.
2. Continue to boot up the P2041 board into Linux. Type "root" to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)mkdir /smbshare/{s1,s2} -p
   - e)chmod -R 777 /smbshare
   - f)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - h)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - i)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - j)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - k)ifconfig fm1-gb0 192.168.1.100/24
   - l)ifconfig fm1-gb1 192.168.2.100/23
   - m)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - n)ethtool –K fm1-gb0 gro on gso on sg on
   - o)ethtool –K fm1-gb1 gro on gso on sg on

   If you want to use EXT4 file system, change above command b) c) to:

- b') mkfs.ext4 /dev/md0
- c') mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On each NAS client side, map the shared folders /smbshare/{s1,s2} as 2 windows drive, e.g, drive Z, and drive Y. Please refer to the below steps for details, then you will get 2 new drive as figure 3.6.2.
   - a)Connect the NAS client and the board directly by 2 crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx/24 and 192.168.2.yyy/23
   - c)Open a command prompt window on NAS client and input the following command to map the shared folders as 2 windows drives:
     - Net use Z: \\192.168.1.100\public\s1
     - Net use Y: \\192.168.2.100\public\s2

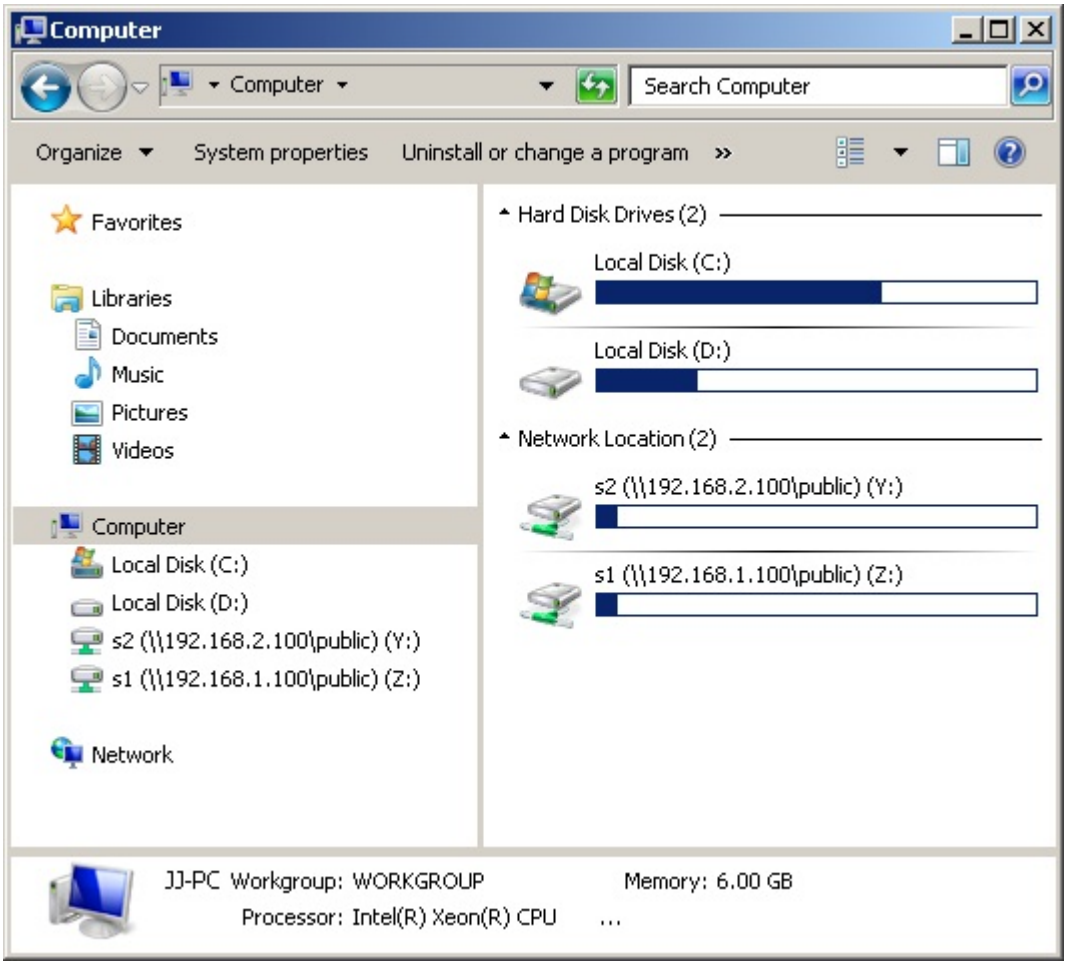

Figure 403. Figure 3.6.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.

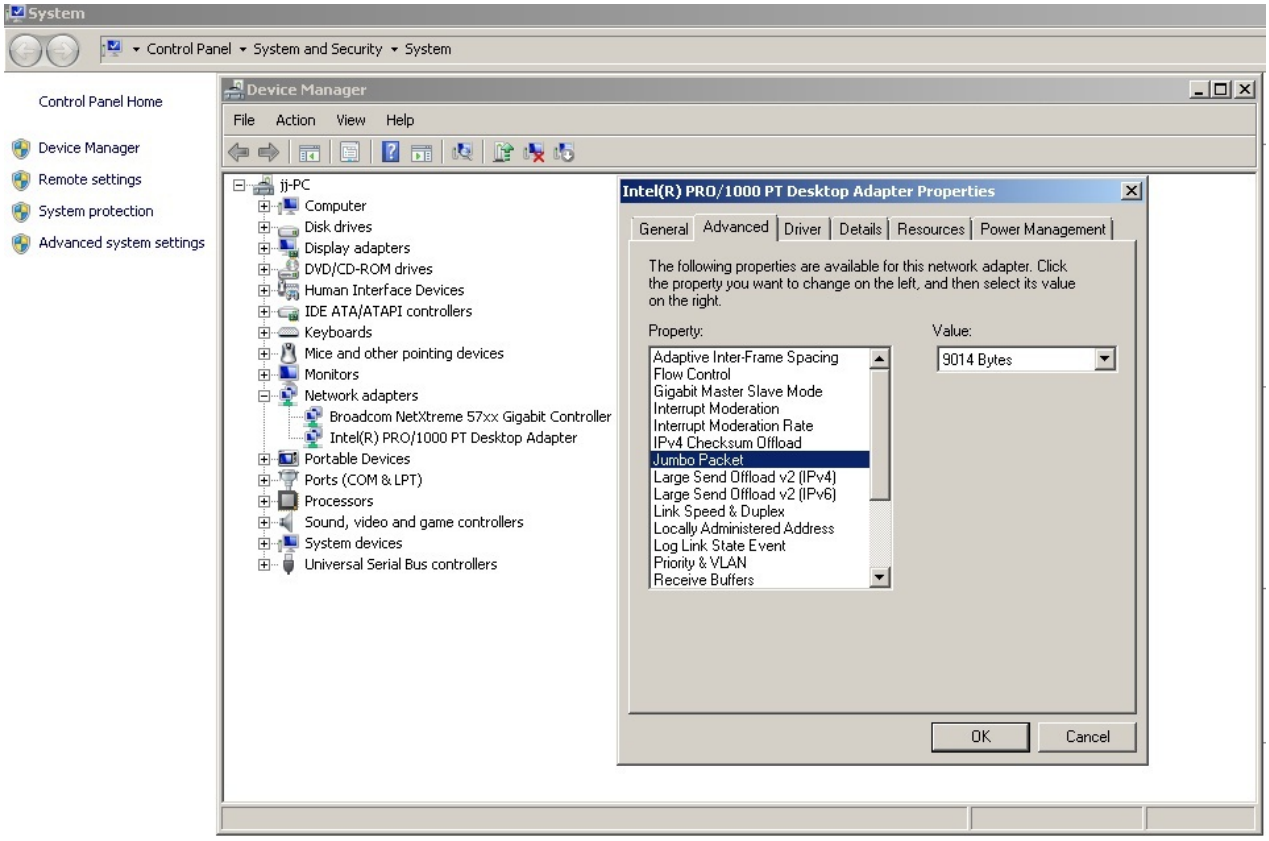

Figure 404. Figure 3.6.3

- a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel->System and Security->System->Device Manager->" Intel(R) PRO/1000 PT Quad Port Server Adapter " and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.6.3.
- b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
  - # ifconfig fm1-gb0 mtu 9014
  - # ifconfig fm1-gb1 mtu 9014

7. Generate 2 dummy files with 2GB with the following command in two NAS client side command prompt windows, it's better put the two files in different hard disk:
   - prompt> fsutil file createnew 2G.001 2147483648
   - prompt> fsutil file createnew 2G.002 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy C:\ Z:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy D:\ Y:\ 2G.002 /NP /NS /COPY:D
   - To test reading performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy Z:\ C:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy Y:\ D:\ 2G.002 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.

- b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
- c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.6.4 shows:

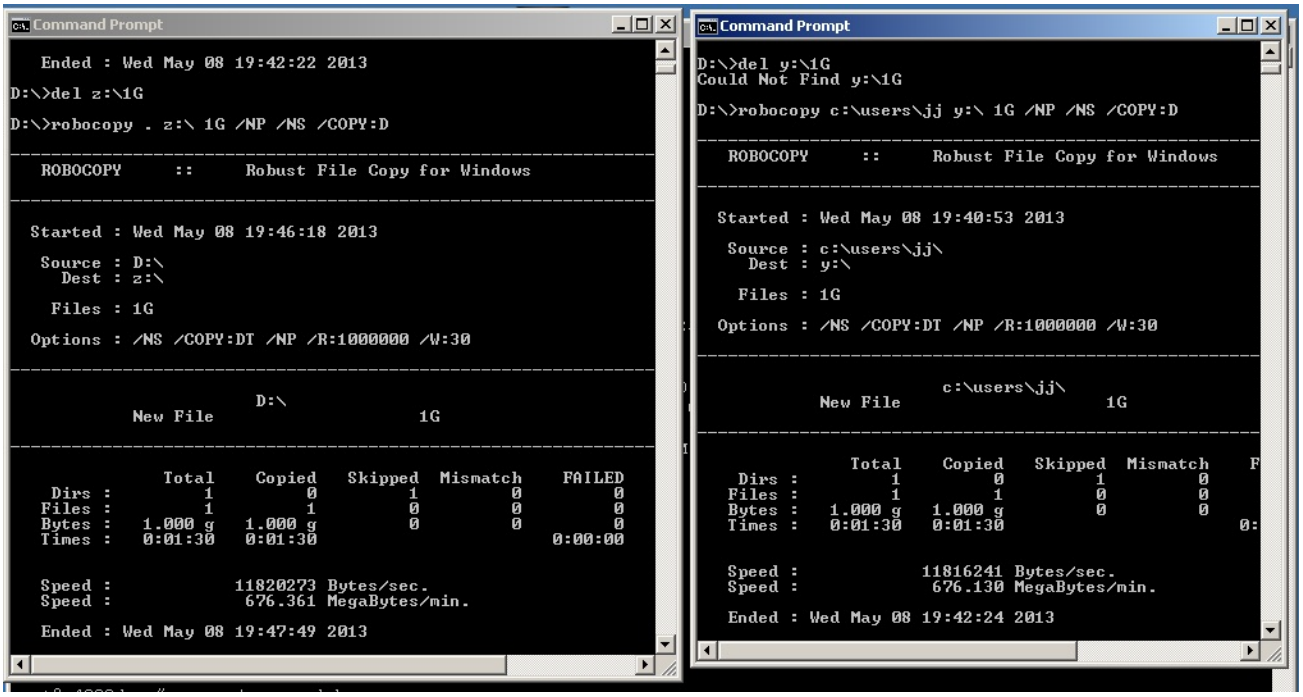

Figure 405. Figure 3.6.4

Here are the example robocopy results of reading 1G file in 2 command prompt windows of the NAS client. The numbers are 676.361 MegaBytes/min and 676.130 MegaBytes/min. It means the 1st client reading speed is about 11MB/s that can be computed by (676.361 MegaBytes/min) / (60second/min) and the 2nd client reading speed is about 11MB/s that can be computed by (676.130 MegaBytes/min) / (60 second/min). You should calculate the last result by adding two single client result:

The last result = $\sum_{i=1}^{2} result\ \ in\ \ client_i$ = 11MB/s +11MB/s =22MB/s

12.2.8.3.7 Four-core RAID5 four-client

Hardware setup

4 SATA disks will be needed for RAID5. You can compose RAID5 on P2041RDB with 2 PCIe-SATA adaptors. The network connection is shown below.

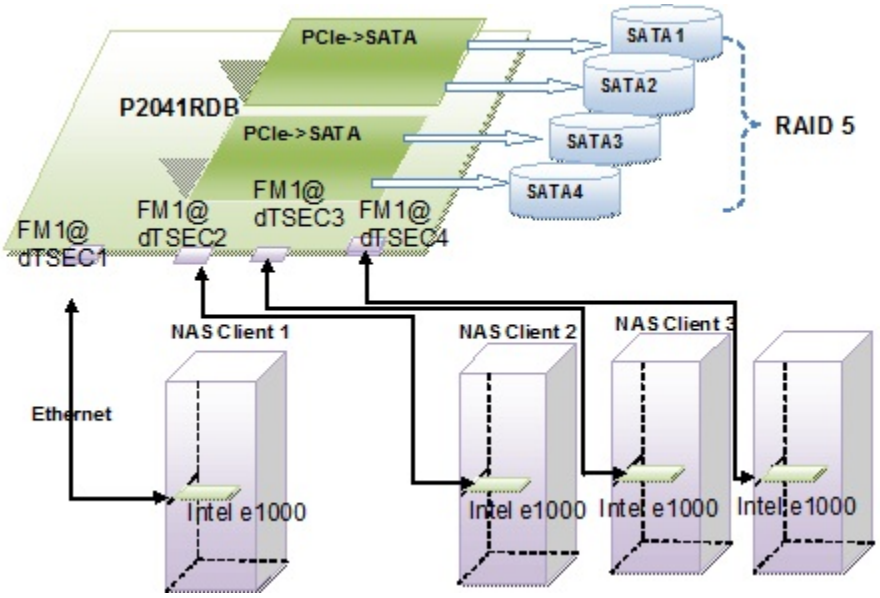

Figure 406. Method 1 is as figure 3.7.1:

Test procedures

Please follow the below steps to have RAID5/two-client NAS performance test:

1. Power on the P2041 board and make sure 4 cores enabled.
2. Continue to boot up the P2041 board into Linux. Type "root" to enter the Linux command line.
3. Setup RAID5, shared folder and IP address on P2041 board with below command. Suppose the shared folder is /smbshare, and EXT2 is used:
   - a)mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1
   - b)mkfs.ext2 /dev/md0
   - c)mount /dev/md0 /smbshare
   - d)mkdir -p /smbshare/{s1,s2,s3,s4}
   - e)chmod -R 777 /smbshare
   - f)echo 512 > /sys/block/sda/bdi/read_ahead_kb
   - g)echo 512 > /sys/block/sdb/bdi/read_ahead_kb
   - h)echo 512 > /sys/block/sdc/bdi/read_ahead_kb
   - i)echo 512 > /sys/block/sdd/bdi/read_ahead_kb
   - j)echo 1024 >/sys/block/md0/md/stripe_cache_size
   - k)ifconfig fm1-gb0 192.168.1.100/24
   - l)ifconfig fm1-gb1 192.168.2.100/23
   - m)ifconfig fm1-gb2 192.168.4.100/22
   - n)ifconfig fm1-gb3 192.168.8.100/21
   - o)fmc –c NAS_cfg_P4080_P5020_P5040_P3041_P2041_P2040.xml –p NAS_policy_P4080_P5020_P5040_P3041_P2041_P2040.xml -a
   - p)ethtool –K fm1-gb0 gro on gso on sg on

- q)ethtool –K fm1-gb1 gro on gso on sg on
- r)ethtool –K fm1-gb2 gro on gso on sg on
- s)ethtool –K fm1-gb3 gro on gso on sg on

If you want to use EXT4 file system, change above command b) c) to:

- b') mkfs.ext4 /dev/md0
- c') mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

4. Startup Samba service on board side with command:
   - smbd –s /etc/samba/smb.conf
5. On each NAS client side, map the shared folder /smbshare as 4 windows drives, e.g, drive Z, drive Y, drive X, drive W. Please refer to the below steps for details, then you will get 4 new drive as figure 3.7.2.
   - a)Connect the NAS client and the board directly by 4 crossover network cable.
   - b)Set up the NAS client IP to 192.168.1.xxx/24 ,192.168.2.yyy/23, 192.168.4.zzz/22, and 192.168.8.www/21
   - c)Open a command prompt window on NAS client and input the following command to map the shared folders as 4 windows drives:
     - Net use Z: \\192.168.1.100\public\s1
     - Net use Y: \\192.168.2.100\public\s2
     - Net use X: \\192.168.4.100\public\s3
     - Net use W: \\192.168.8.100\public\s4

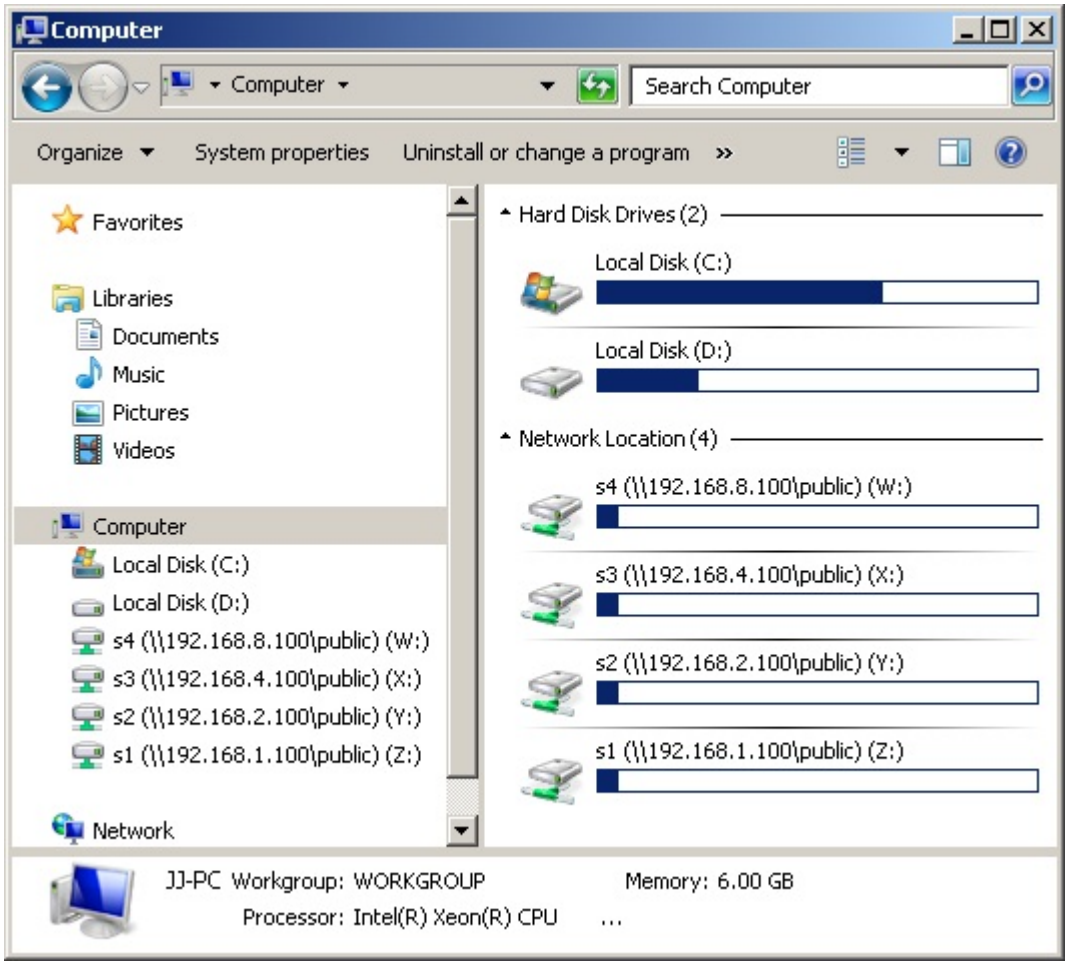

Figure 407. Figure 3.7.2

6. Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step if you want to keep the default 1500 Bytes MTU.
   - a)At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel->System and Security->System->Device Manager->" Intel(R) PRO/1000 PT Quad Port Server Adapter " and configure Jumbo Packets as 9014 bytes. Please refer to Figure 3.7.3.
   - b)At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:
     - # ifconfig fm1-gb0 mtu 9014
     - # ifconfig fm1-gb1 mtu 9014
     - # ifconfig fm1-gb2 mtu 9014
     - # ifconfig fm1-gb3 mtu 9014

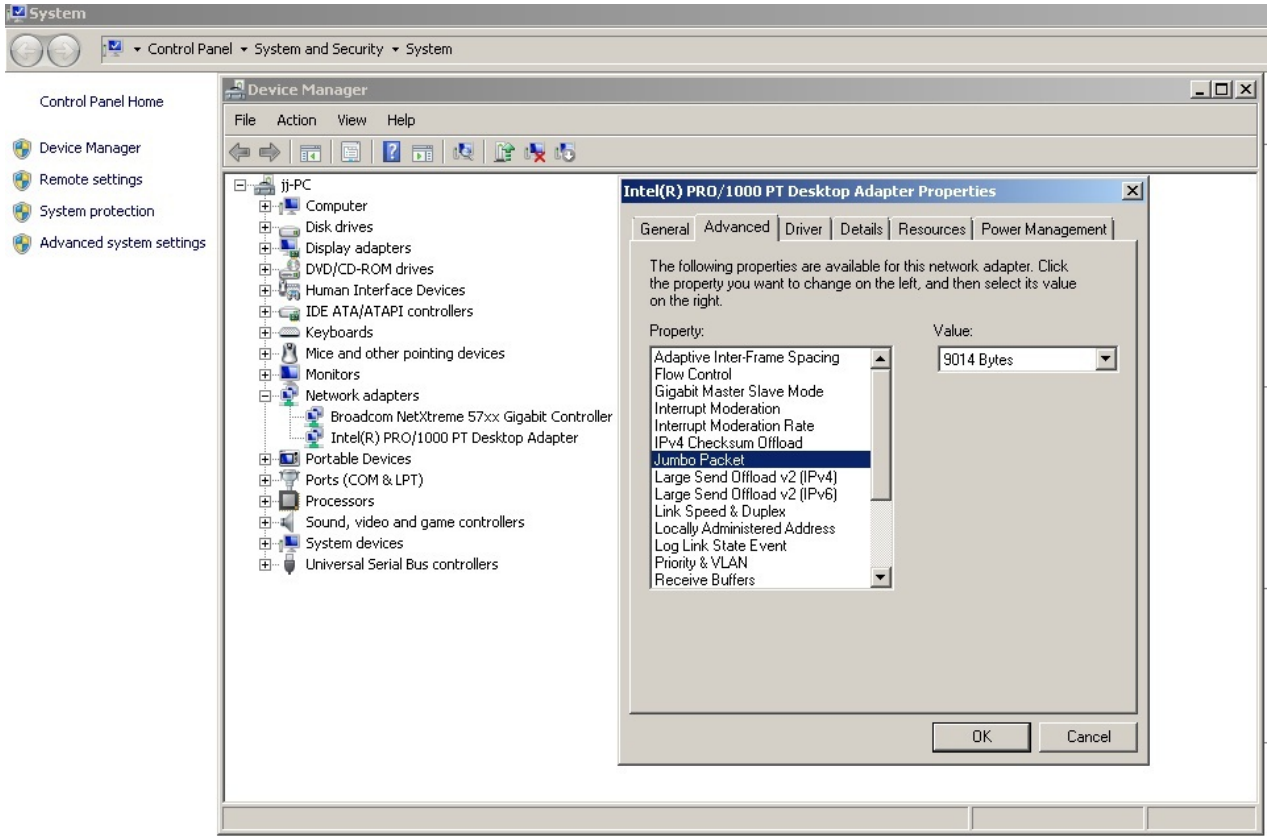

Figure 408. Figure 3.7.3

7. Generate 4 dummy files with 2GB with the following command in 4 NAS client side command prompt windows, it's better put the 4 files in different hard disk:
   - prompt> fsutil file createnew 2G.001 2147483648
   - prompt> fsutil file createnew 2G.002 2147483648
   - prompt> fsutil file createnew 2G.003 2147483648
   - prompt> fsutil file createnew 2G.004 2147483648
8. Begin the test with below commands at NAS client side:
   - To test writing performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy C:\ Z:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy D:\ Y:\ 2G.002 /NP /NS /COPY:D
     - Run the following command in the 3rd command prompt window: prompt> robocopy E:\ X:\ 2G.003 /NP /NS /COPY:D
     - Run the following command in the 4th command prompt window: prompt> robocopy F:\ W:\ 2G.004 /NP /NS /COPY:D
   - To test reading performance:
     - Run the following command in the 1st command prompt window: prompt> robocopy Z:\ C:\ 2G.001 /NP /NS /COPY:D
     - Run the following command in the 2nd command prompt window: prompt> robocopy Y:\ D:\ 2G.002 /NP /NS /COPY:D
     - Run the following command in the 3rd command prompt window: prompt> robocopy X:\ E:\ 2G.003 /NP /NS /COPY:D
     - Run the following command in the 4th command prompt window: prompt> robocopy W:\ F:\ 2G.004 /NP /NS /COPY:D
9. Recording the performance number:
   - a)To warm up the testing, it is better drop the first result.

- b)To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.
- c)Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the result

You are expected to get the result something like the below Figure 3.7.4 shows:

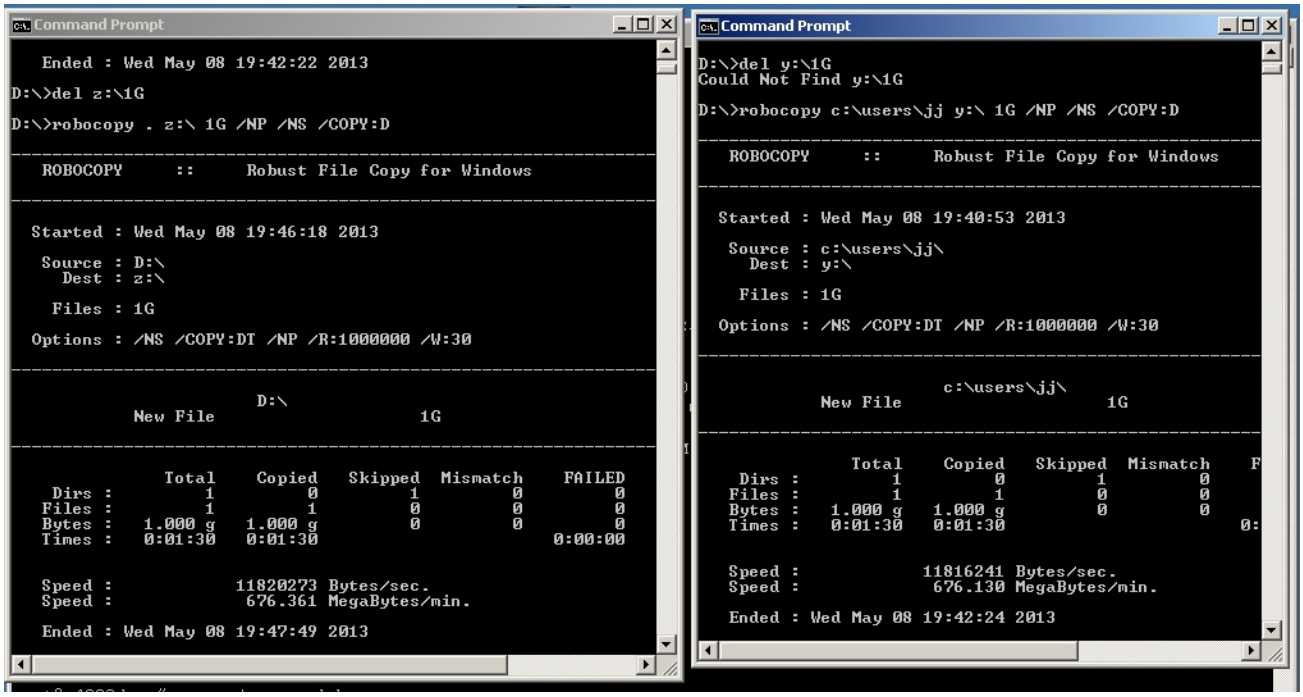

Figure 409. Figure 3.7.4

Here are the example robocopy results of reading 1G file in 2 command prompt windows of the NAS client. In fact, you should have 4 command prompt windows and 4 testing results.

The 1st NAS client result is (676.361 MegaBytes/min) / (60second/min) = 11MB/s

The 2nd NAS client result is (676.130 MegaBytes/min) / (60 second/min) =11 MB/s

The 3rd NAS client result is…

The 4th NAS client result is…

You should calculate the last result by adding 4 single client result:

The last result = $\sum_{i=1}^{4} result\ in\ client_i$ =result1 + result2 + result3 + result 4

12.2.8.4 Appendix

This section describes NAS PCD files, the FQID base table, client scripts, and the SAMBA configuration file.

12.2.8.4.1 NAS PCD files

PCD config file

```
<cfgdata>
<config>
<engine name="fm0">
<port type="1G" number="0" policy="fm1_gb0_NAS_policy"/>
<port type="1G" number="1" policy="fm1_gb1_NAS_policy"/>
<port type="1G" number="2" policy="fm1_gb2_NAS_policy"/>
<port type="1G" number="3" policy="fm1_gb3_NAS_policy"/>
<port type="1G" number="4" policy="fm1_gb4_NAS_policy"/>
<port type="10G" number="0" policy="fm1_10g_NAS_policy"/>
</engine>
<engine name="fm1">
<port type="1G" number="0" policy="fm2_gb0_NAS_policy"/>
<port type="1G" number="1" policy="fm2_gb1_NAS_policy"/>
<port type="1G" number="2" policy="fm2_gb2_NAS_policy"/>
<port type="1G" number="3" policy="fm2_gb3_NAS_policy"/>
<port type="1G" number="4" policy="fm2_gb4_NAS_policy"/>
<port type="10G" number="0" policy="fm2_10g_NAS_policy"/>
</engine>
</config>
</cfgdata>
<!-- end of PCD config file-->
```

NOTE

if you do not use some network interface, please make sure to delete those network interface in the PCD config files accordingly.

12.2.8.4.2 FQID base table

FQID base calculation

This table is only a demo for FQID base calculation, please refer to the latest version of "*Core Affined Queues*" within the NXP linux_ethernet_driver documentation.

Table 611. FMAN v2 devices core affined queues

Interface	FQID base	P4080	P5020	P5040	P3041	P2041
fm1-gb0	0x3800	Y	Y	Y	Y	Y
fm1-gb1	0x3880	Y	Y	Y	Y	Y
fm1-gb2	0x3900	Y	Y	Y	Y	Y
fm1-gb3	0x3980	Y	Y	Y	Y	Y
fm1-gb4	0x3a00		Y	Y	Y	
fm1-10g	0x3c00	Y	Y	Y		
fm2-gb0	0x7800	Y		Y		
fm2-gb1	0x7880	Y		Y		
fm2-gb2	0x7900	Y		Y		
fm2-gb3	0x7980	Y		Y		
fm2-gb4	0x7a00			Y		
fm2-10g	0x7c00	Y		Y		

Table 612. FMAN v3 devices core affined queues

Interface	FQID base	T4240	T4160	B4860	B4420
fm1-mac1	0x3800	Y	Y	Y	Y
fm1-mac2	0x3880	Y	Y	Y	Y
fm1-mac3	0x3900	Y	Y	Y	Y
fm1-mac4	0x3980	Y	Y	Y	Y
fm1-mac5	0x3a00	Y	Y	Y	
fm1-mac6	0x3a80	Y	Y	Y	
fm1-mac9	0x3c00	Y	Y	Y	
fm1-mac10	0x3c80	Y		Y	
fm2-mac1	0x7800	Y	Y		
fm2-mac2	0x7880	Y	Y		
fm2-mac3	0x7900	Y	Y		

Table continues on the next page...

Table 612. FMAN v3 devices core affined queues (continued)

Interface	FQID base	T4240	T4160	B4860	B4420
fm2-mac4	0x7980	Y	Y		
fm2-mac5	0x7a00	Y	Y		
fm2-mac6	0x7a80	Y	Y		
fm2-mac9	0x7c00	Y	Y		
fm2-mac10	0x7c80	Y			

12.2.8.4.3 NAS client test scripts

NAS client test scripts for 1 client

This test script is only for 1 client and 4GByte files reading and writing benchmarking, for 2,4 or more client or other size files, the script should be modified accordingly.

Robocopy_4G_file.bat

```
echo ----------Write----------
del z:\4G
robocopy . z:\ 4G /NP /NS /COPY:D
del z:\4G
robocopy . z:\ 4G /NP /NS /COPY:D

```

12.2.8.4.4 SAMBA config file

smb.conf

```
#make sure to enable requiring network interface in the [global] section and in the interfaces fields.
[global]
interfaces = fm1-gb0, fm1-gb2, fm1-gb3, fm1-gb4
map to guest = Bad User
client NTLMv2 auth = Yes
client lanman auth = No
client plaintext auth = No
max xmit = 2097152
socket options = TCP_NODELAY IPTOS_LOWDELAY SO_RCVBUF=262142
SO_SNDBUF=262142
dns proxy = No
#For 64bit kernel, please set use sendfile = No.
use sendfile = Yes
guest account = root
pre-reply write = No
min receivefile size = 1
dos charset = UTF-8
unix charset = UTF-8
display charset = UTF-8
[public]
path = /smbshare
read only = No
guest ok = Yes
```

12.2.8.5 Known Bugs, Limitations, or Technical Issues

1. NAS can't reading bigger than 2GB files while set "use sendfile = Yes" in smb.conf on DPAA platform 64bit.Workaround:modify smb.conf file, set "use sendfile = No".
2. Out of memory (OOM) situations:OOM sometimes occurs when storage systems and heavy network traffic are used at the same time. Linux kernel uses the Page Cache mechanism to cache in the main memory data ultimately intended for disk storage. Dedicated flusher threads will fetch the dirty cached pages from the main memory and, when the kernel permits, write them on the disk. This greatly increases the performance of the average systems that do not issue gigabyte transfers in short time bursts. In NAS case, network ports are used for network file transfer. Because of this, the flusher threads are not able to free the main memory fast enough to be used by other kernel applications, like Ethernet driver's softirq. In order to optimize the kernel to support write-heavy operations, some tweaks should be made to the kernel virtual machine to improve responsiveness and aggressiveness of the page cache manager. These optimizations are well documented in the kernel documentation pages (Documentation/sysctl/vm.txt). For NAS application, the parameter that forces the Linux LVM to keep a minimum number of kilobytes free in lowmem and the one that controls the aggressiveness of the kernel to reclaim memory used for caching were modified. "echo 10000 > /proc/sys/vm/min_free_kbytes echo 200 > /proc/sys/vm/vfs_cache_pressure" With above modifications, the OOM often disappears, the system achieves necessary balance between caching and memory availability. Although some of the parameters have a great impact on the system behavior, some of them are not scalable or may actually hurry the appearance of the OOM situation. For example, this can happen when setting the min_free_kbytes to a very high value. It should be also noted that the overall performance of the system during write-heavy operations greatly depends on the disk operation speed, which, as in most current architectures, is the system's bottleneck. Other systems and applications that do not behave satisfactorily with the kernel default values should use their own empirical values. https://www.kernel.org/doc/Documentation/sysctl/vm.txt http://www.westnet.com/~gsmith/content/linux-pdflush.htm
3. NAS (SAMBA) write performance sometimes are not stable enough even with the same hard environment, the same software environment and the same test steps according hundreds of observation. The best performance sometimes are +20% better than the worst performance. Many factors result in such a phenomenon, such as hard disks aging, hard disk cache size and other storage factor. In order to make the result more stable, more smooth, and easy reproduce, it is recommended to test the same case multiple times, more than 20 times is plus, then average those 20 times specimen as the last benchmarking result.

12.2.9 NAS - eTSEC

How to setup a NAS system on NXP QorIQ/LayerScape system, and how to measure its performance.

12.2.9.1 Benchmarking objectives

The purpose of this guide is to show how to setup a NAS system on a NXP QorIQ/LayerScape processor based system and how to measure its performance.

NOTE

LS1021ATWR was used for the demo. Please refer to the board's manual for other boards.

12.2.9.2 Test Environment

NAS Client

The suggested NAS client is described in table 1. The client has high throughput performance to make sure the testbed would not limit the NAS performance. Any degradation to the suggested NAS client may lead to degradation of overall NAS performance.

Table 613. NAS client configuration

Item	Description
CPU	Minimum requires Intel® i5 CPU 750@2.67 GHz
RAM	4G DDR3 RAM
Hard Drives	Western Digital® WD3000HLFS 10000 RPM,Two drives configured in RAID 0 array
Ethernet	Standalone Intel PRO/1000 PT Desktop Adapter (PCIE)
OS	Microsoft® Windows® 7 (32bit) or Microsoft Windows Vista®
Anti-virus software	off
Firewall software	off
Connection to NAS server	Direct connection through Ethernet cable without switches

NAS server

In this document, the NAS benchmark will be done on the LS1021ATWR. For details, please refer to user manual of the board.

The SATA disk being used is Western Digital WD3000HLFS, 10000RPM. If lower speed SATA is used, it will impact the overall NAS performance.

LS1021ATWR has only 1 onboard SATA connector, which is not enough to compose RAID5 array. Therefore, 2 ports PCIe to SATA adaptor will be used for RAID5 tests.

See Table 2 for details.

Table 614. NAS server configuration

Item	Description
Silicon and board	LS1021ATWR
RCW	RSR_PPS_70:rcw_1000.bin RSR_PPS_70 means: - RGMII@EC1 - SGMII@EC2 - RGMII@EC3 - PCIe*1 on slot 1 - PCIe*1 on slot 2 - SATA - SERDES1 Protocol is 0x70
RAM	1 G DDR3 RAM
Hard Drives	Western Digital WD3000HLFS 10000 RPM, Single drive, four drives configured in RAID 5 array or 2 drives configured in RAID0
Ethernet	Onboard VeTSEC
PCIe-SATA adaptor	Silicon Image 3132
MTU setting	MTU=1500, 9014
OS	Linux BSP, kernel version 4.1.8

Measurement

File copy under Windows7

The tests are done using the robocopy command built into Microsoft Windows 7 (and available as a download as part of the free Microsoft Windows Server® 2003 Resource Kit Tools).

The benchmarks consist of Write and Read transfers of a single file which size is 2 GB. The separate RAID 0 array in the NAS testbed is specifically designed to support this test.

12.2.9.3 Test Procedure

RAID5 NAS hardware setup

4 SATA disks are required for RAID5. You can compose RAID5 array on target QorIQ platform with a PCIe-SATA adapter and on-board SATA controllers. Please connect the board, PCIe-SATA adapter and SATA disks are as figure 1.

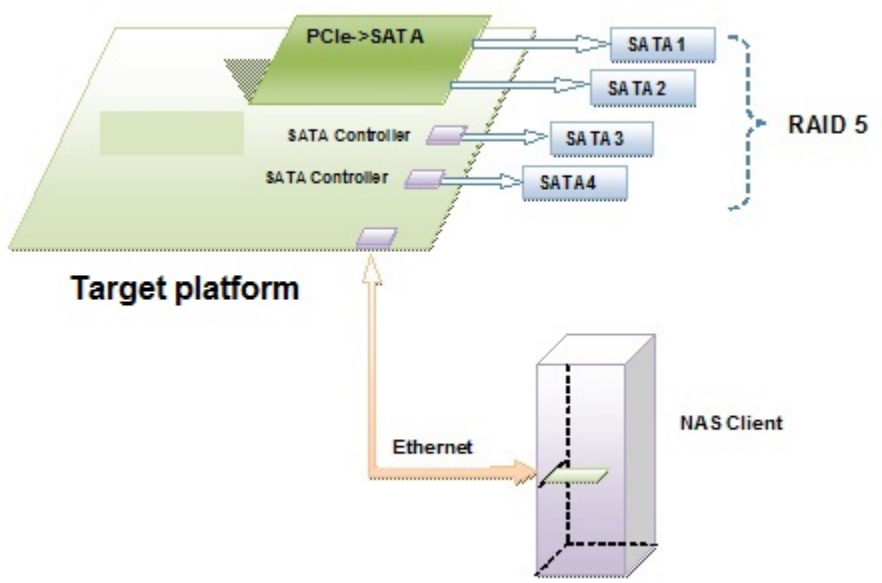

Figure 410. Connecting PCIe-SATA adapter and SATA disks

An alternative way: Compose RAID5 with 2 PCIe-SATA adapters on ls1021atwr, as shown in figure 2. This method is preferred since it is easy to reproduce.

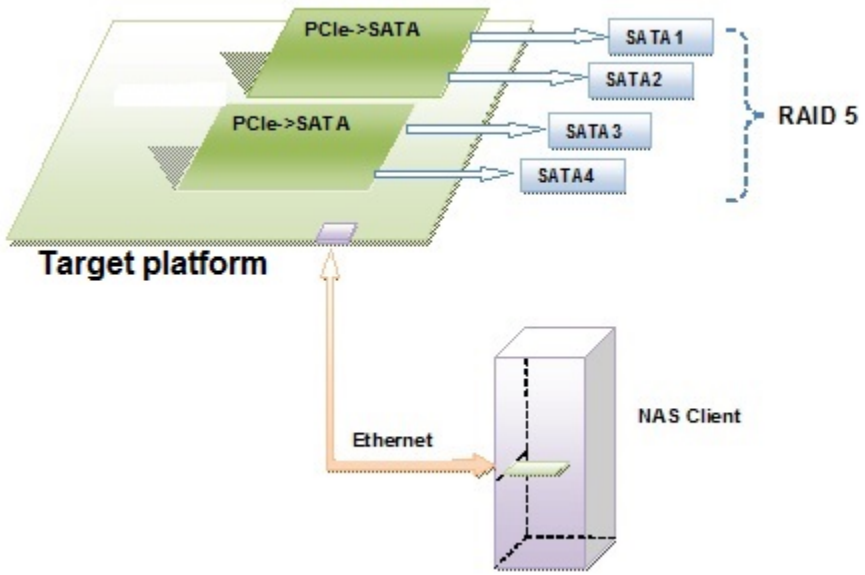

Figure 411. Using two PCIe-SATA adapters

Connect the board with NAS server via Ethernet, and now you have a NAS system.

RAID5 NAS test procedures

The default non-dpaa kernel configure does not support RAID5, In order to enabe RAID5 support and to make sure the best RAID5 local access performance, please refer to NXP Linux RAID reproducibility guide.

Please follow the below steps to have RAID5 NAS test:

1.Boot up the target QorIQ platform. Type “root” to enter the Linux command line.

2.Setup RAID5 on target QorIQ platform with below command. Suppose the shared folder is /smbshare, and EXT2 is used:

a) #mdadm -C /dev/md0 -amd -R -l5 -n4 /dev/sd[abcd]1

b) #mkfs.ext2 /dev/md0

c) #mount /dev/md0 /smbshare

d) #echo 512 > /sys/block/sda/bdi/read_ahead_kb

e) #echo 512 > /sys/block/sdb/bdi/read_ahead_kb

f) #echo 512 > /sys/block/sdc/bdi/read_ahead_kb

g) #echo 512 > /sys/block/sdd/bdi/read_ahead_kb

h) #echo 1024 >/sys/block/md0/md/stripe_cache_size

i) #ethtool -C eth[0,1] tx-frames 22 tx-usecs 32 (This step is needed only by mtu=1500)

j) #ethtool -C eth[0,1] rx-frames 22 rx-usecs 32 (This step is needed only by mtu=1500)

k) #ethtool -K eth[0,1] gro on gso on sg on

l) set CPU load automatically balance at ls1021atwr platform:

```
#cp /etc/samba/Heavy_Load_Assistant4LS1021A_NAS.sh ~/
#cd ~/
#chmod +x ./Heavy_Load_Assistant4LS1021A_NAS.sh
#./Heavy_Load_Assistant4LS1021A_NAS.sh auto &
```

```
Input below commands to restore default system setting at any time as will:
#killall -9 Heavy_Load_Assistant4LS1021A_NAS.sh
#cp /etc/samba/Heavy_Load_Assistant4LS1021A_NAS.sh ~/
#cd ~/
#chmod +x ./Heavy_Load_Assistant4LS1021A_NAS.sh
#./Heavy_Load_Assistant4LS1021A_NAS.sh restore
```

If you want to use EXT4 file system, change command line b) & c) to:

b') #mkfs.ext4 /dev/md0

c') #mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /smbshare

Startup Samba service on board side with command:

#smbd –s /etc/samba/smb.conf

On NAS client side, map the shared folder /smbshare as a windows drive, e.g, drive z. Please refer to the below steps a) to d) and figure 3, figure 4 for details.

a) Config NAS client and target QorIQ platform IP in the same network segment, e.g. 192.168.1.xxx

b) Connect the NAS client and the board directly by a wired network cable.

c) Enter board IP in the NAS client explorer window, such as \\192.168.1.100, then a folder named "public Share" will be shown.

d) Right click the folder "public Share", select "Map network drive…"in the popup menu. See Figure 3.

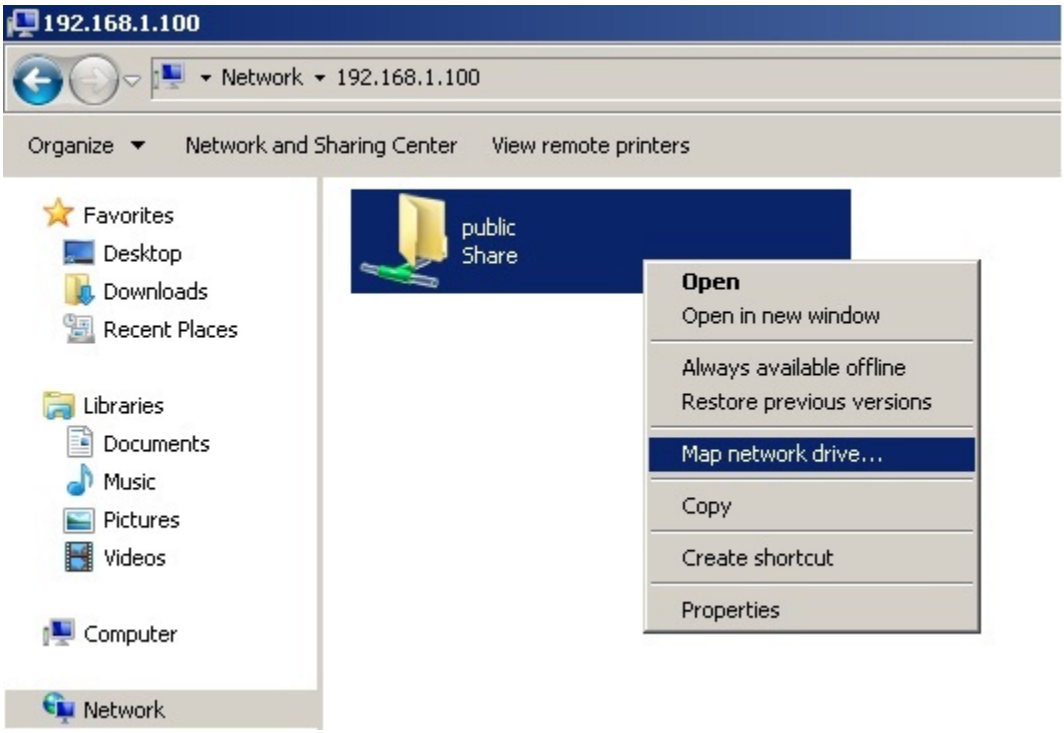

Figure 412. Selecting network driver

e) Click Finish, then the shared folder of NAS server is now mapped as a Windows drive Z. See Figure 4.

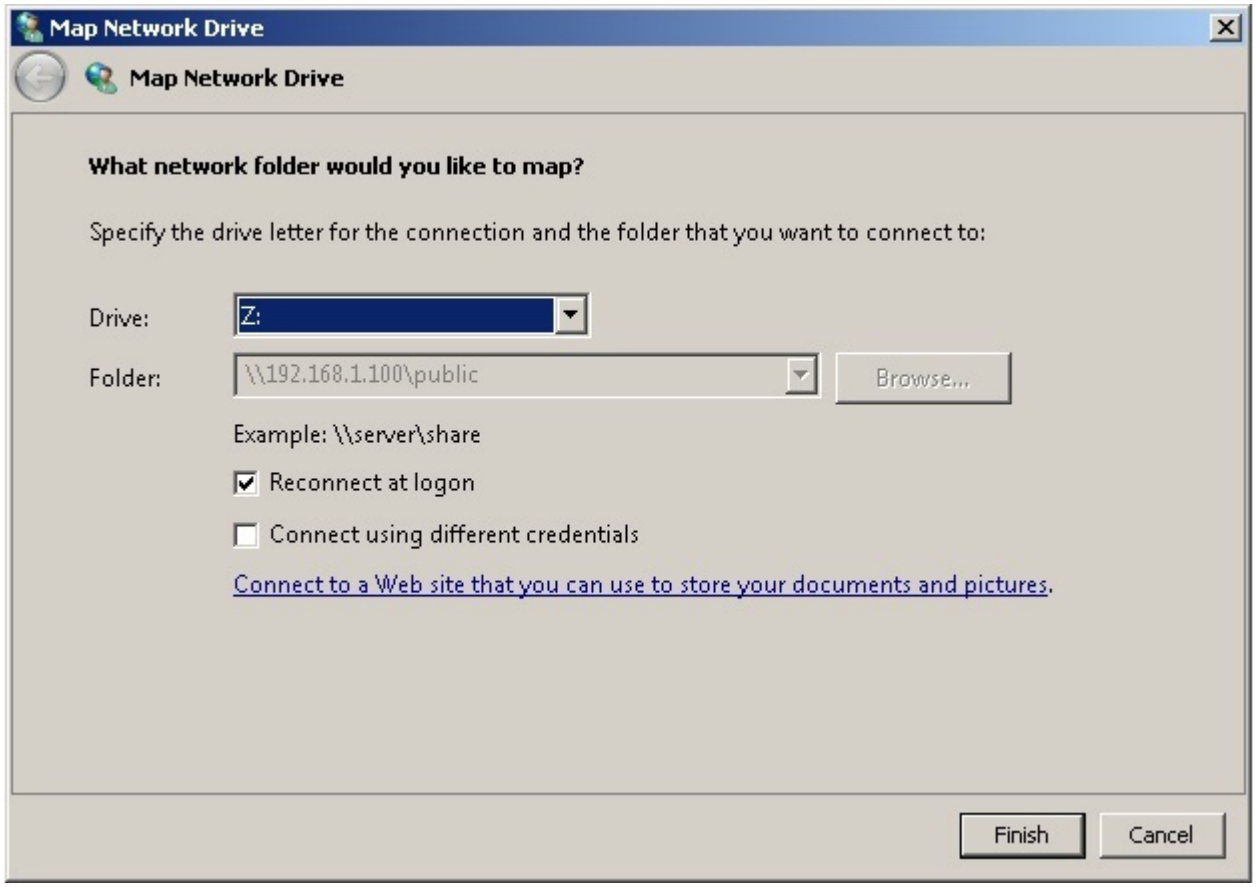

Figure 413. shared folder of NAS server mapped as Windows Drive Z

5.Setup up jumbo frame on both client and server side. With jumbo frame, better NAS performance can be achieved. Please skip this step and step 2.k) if you want to keep the default frame size, which is 1.5K.

a) At the NAS client (windows 7) side, open network and sharing center by selecting Start-> Settings-> Control Panel->System and Security->System->Device Manager->Intel(R) PRO/1000 PT Desktop Adapter and configure Jumbo Packets as 9014 bytes. Please refer to Figure 5.

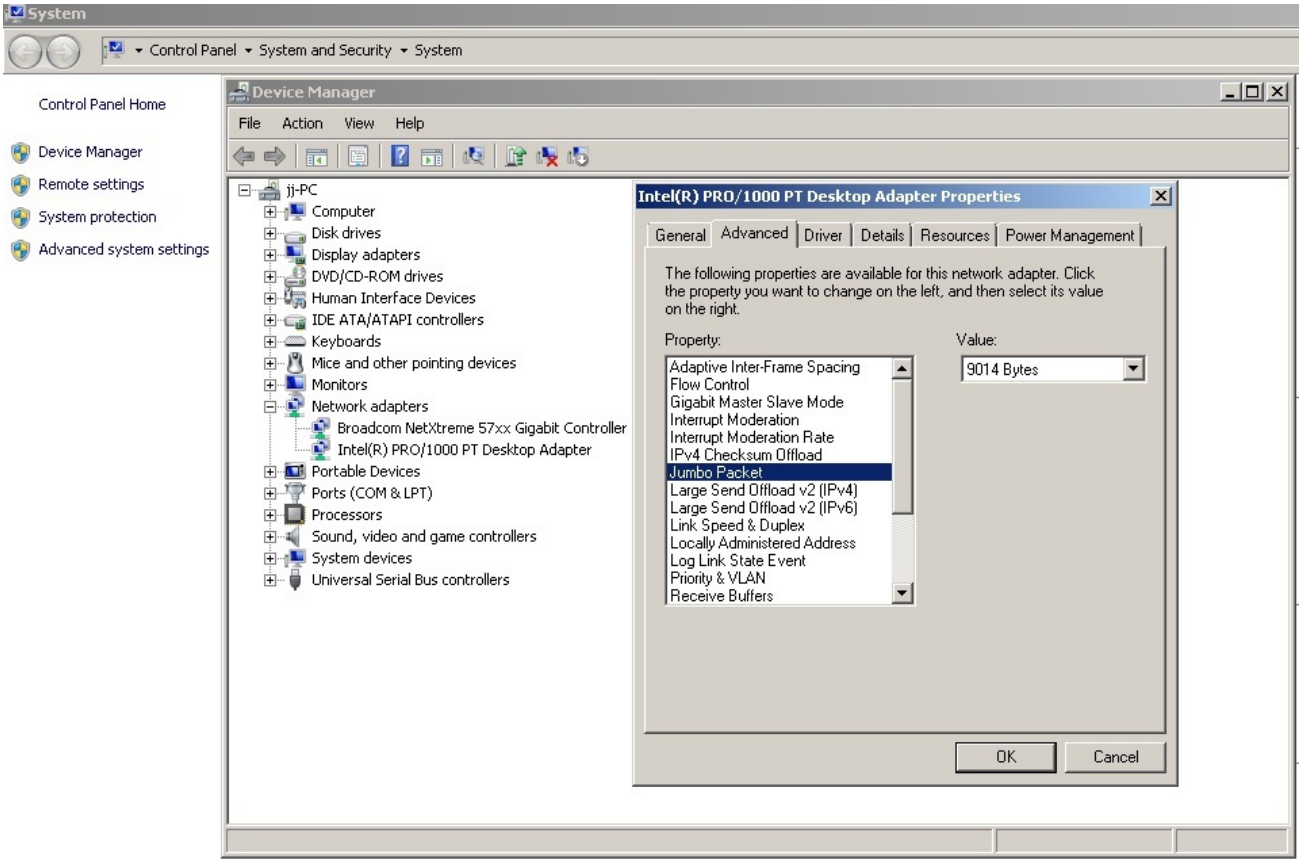

Figure 414. Jumbo Frame enablement

b) At the NAS server (Linux) side, config the ethernet MTU to 9014 with command:

ifconfig eth0 mtu 9014

6.Generate a dummy file with 2GB in size with the following command at NAS client side:

fsutil file createnew 2G.001 2147483648

7.Begin the test with below commands at NAS client side:

To test writing performance:

robocopy . z:\ 2G.001 /NP /NS /COPY:D

To test reading performance:

robocopy z:\ . 2G.001 /NP /NS /COPY:D

8.IMPRORTANT: Tips for getting the performance number:

a) To warm up the testing, it is better drop the first result.

b) To reduce the impact of the fluctuation among the tests, it's better test the same scenario more than 5 times and use the average number.

c) Between tests, it is better to wait for more than 30 seconds so that the cached pages are flushed to the disk.

Understanding the RAID5 NAS result

You are expected to get the result something like the below Figure 6 shows:

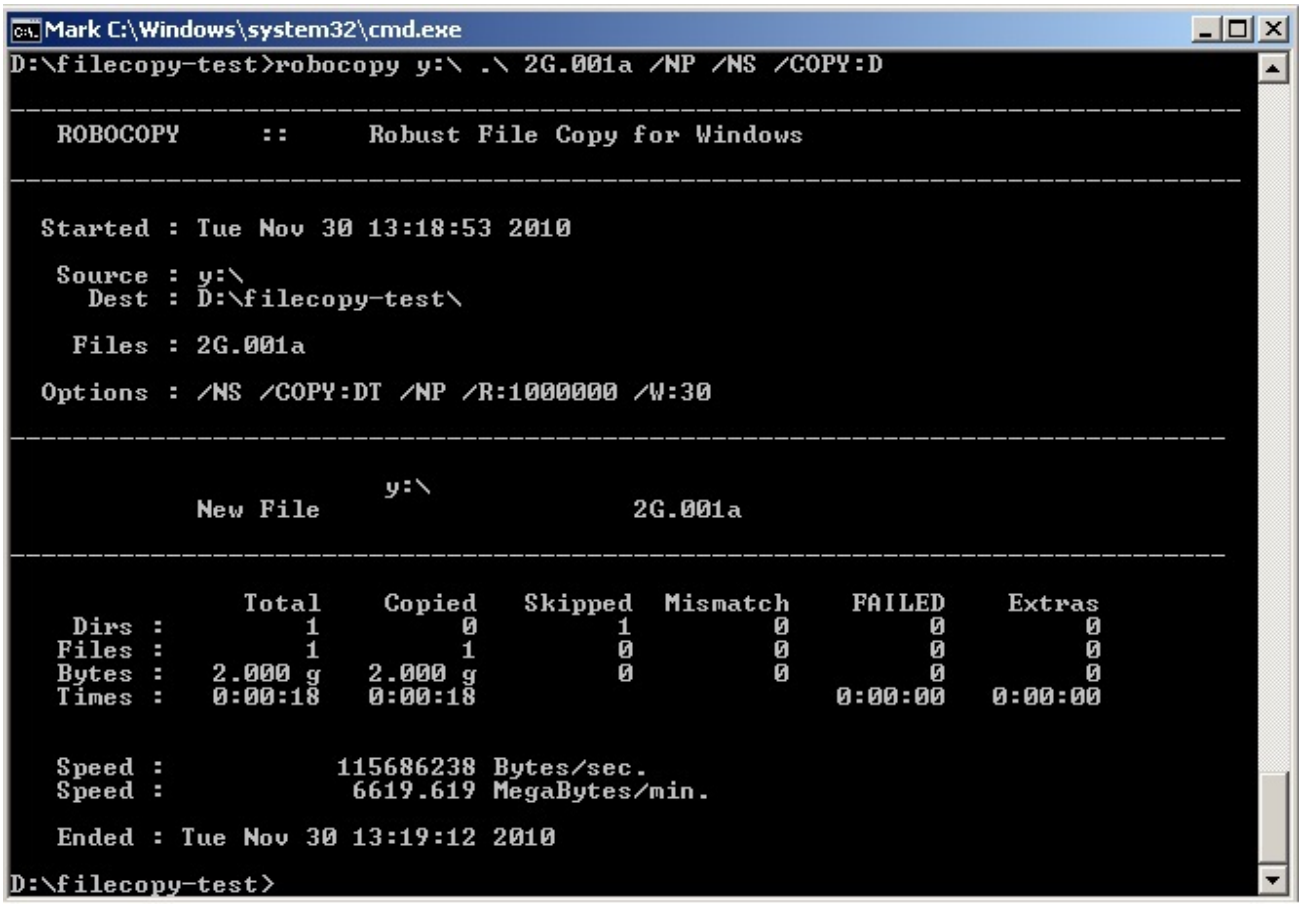

Figure 415. ROBOCOPY result

Here is the example robocopy result of reading 2G file. The number is 6619.619 MegaBytes/min. It means the reading speed is about 110MB/s that can be computed by 6619.619/60.

Single Disk NAS hardware setup

You can also connect the a single disk to on-board SATA controller (Figure 8) or to Silicon Image PCIe-SATA adapter (Figure 9) on ls1021atwr board, and benchmark the NAS performance of single disk.

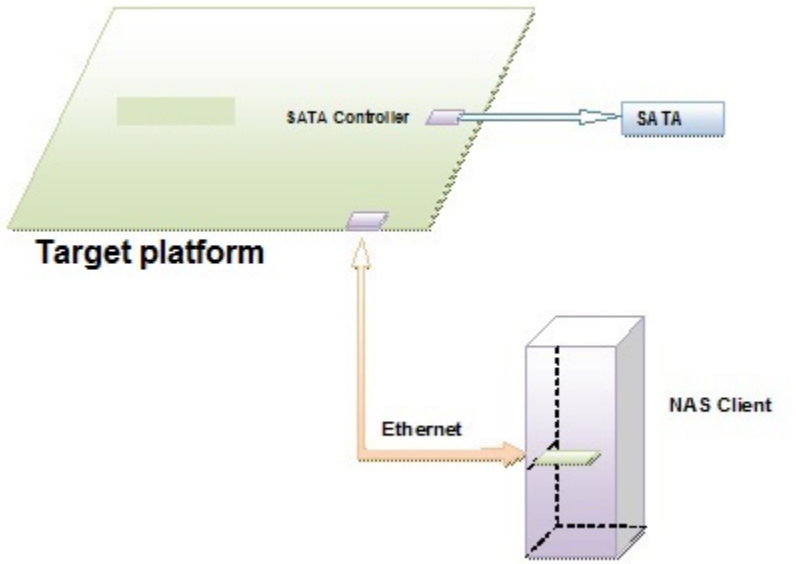

Figure 416. Soc Single SATA Disk NAS

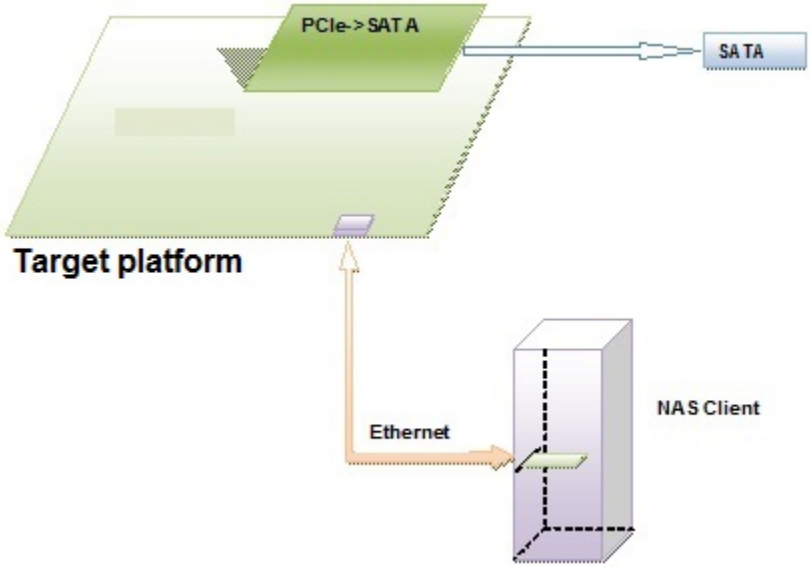

Figure 417. Single PCIe-SATA Disk NAS

Single disk NAS test procedures

Please follow below steps to benchmark single disk NAS performance:

1. Boot up the ls1021atwr board. Type “root” to enter the Linux command line.

2. Setup shared folder on ls1021atwr board with below commands. Suppose the shared folder is /smbshare:

a) #mkfs.ext2 /dev/sda1

b) #mount /dev/sda1 /smbshare

c) #echo 512 > /sys/block/sda/bdi/read_ahead_kb

d) #ethtool -C eth[0,1] tx-frames 22 tx-usecs 32 (This step is needed only by mtu=1500)

e) #ethtool -C eth[0,1] rx-frames 22 rx-usecs 32 (This step is needed only by mtu=1500)

f) #ethtool -K eth[0,1] gro on gso on sg on

g) set CPU load automatically balance at ls1021atwr platform:

```
#cp /etc/samba/Heavy_Load_Assistant4LS1021A_NAS.sh ~/
#cd ~/
#chmod +x ./Heavy_Load_Assistant4LS1021A_NAS.sh
#./Heavy_Load_Assistant4LS1021A_NAS.sh auto &
Input below commands to restore default system setting at any time as will:
#killall -9 Heavy_Load_Assistant4LS1021A_NAS.sh
#cp /etc/samba/Heavy_Load_Assistant4LS1021A_NAS.sh ~/
#cd ~/
#chmod +x ./Heavy_Load_Assistant4LS1021A_NAS.sh
#./Heavy_Load_Assistant4LS1021A_NAS.sh restore
```

If you want to use EXT4 file system, change above command a) b) to:

a') #mkfs.ext4 /dev/sda1

b') #mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/sda1 /smbshare

3. Remaining testing procedures are the same as that of RAID5. Please refer the step 3 to 7 of RAID5 NAS test procedures.

Understanding the single disk NAS result

Please refer to Understanding the RAID5 NAS result. The way of reading the result is the same as that of RAID5.

12.2.9.4 Known Bugs, Limitations, or Technical Issues

1. Since SDK1.4, the RAID5 NAS write performance is significantly lower than SDK1.3 release. This is primarily due to the lack of the "receive file optimization" used in previous releases. Patches are not suitable upstream, so they are not in SDK1.4 and later release.
2. Out of memory (OOM) situations:OOM sometimes occurs when storage systems and heavy network traffic are used at the same time. Linux kernel uses the Page Cache mechanism to cache in the main memory data ultimately intended for disk storage. Dedicated flusher threads will fetch the dirty cached pages from the main memory and, when the kernel permits, write them on the disk. This greatly increases the performance of the average systems that do not issue gigabyte transfers in short time bursts. In NAS case, network ports are used for network file transfer. Because of this, the flusher threads are not able to free the main memory fast enough to be used by other kernel applications, like Ethernet driver's softirq. In order to optimize the kernel to support write-heavy operations, some tweaks should be made to the kernel virtual machine to improve responsiveness and aggressiveness of the page cache manager. These optimizations are well documented in the kernel documentation pages (Documentation/sysctl/vm.txt). For NAS application, the parameter that forces the Linux LVM to keep a minimum number of kilobytes free in lowmem and the one that controls the aggressiveness of the kernel to reclaim memory used for caching were modified.

   ```
   #echo 10000 > /proc/sys/vm/min_free_kbytes
   #echo 200 > /proc/sys/vm/vfs_cache_pressure
   ```

   With above modifications, the OOM often disappears, the system achieves necessary balance between caching and memory availability. Although some of the parameters have a great impact on the system behavior, some of them are not scalable or may actually hurry the appearance of the OOM situation. For example, this can happen when setting the min_free_kbytes to a very high value. It should be also noted that the overall performance of the system during write-heavy operations greatly depends on the disk operation speed, which, as in most current architectures, is the

system's bottleneck. Other systems and applications that do not behave satisfactorily with the kernel default values should use their own empirical values. For details, please refer to:

```
https://www.kernel.org/doc/Documentation/sysctl/vm.txt
http://www.westnet.com/~gsmith/content/linux-pdflush.htm
```

3. NAS (SAMBA) write performance sometimes are not stable enough even with the same hard environment, the same software environment and the same test steps according hundreds of observation. The best performance sometimes are +20% better than the worst performance. Many factors result in such a phenomenon, such as hard disks aging, hard disk cache size and other storage factor. In order to make the result more stable, more smooth, and easy reproduce, it is recommended to test the same case multiple times, more than 20 times is plus, then average those 20 times specimen as the last benchmarking result.
4. In SDK1.8, NAS performance degrades about 20%. This is primarily due to the kernel version upgrade from 3.12.19-rt30 to 3.12.37-rt51. This is tracked by NXP internal CR:ENGR00356091.

12.2.10 Linux RAID

How to setup a Linux RAID system on a NXP QorIQ processor-based system, and how to measure the performance.

12.2.10.1 Benchmarking Objectives

The purpose of this guide is to show how to setup a Linux RAID system on a NXP QorIQ processor based system and how to measure its performance.

12.2.10.2 Test Environment

Hardware Platform Identification

- NXP reference board based on QorIQ series processors
- Hard disks: Western Digital WD3000HLFS 10000RPM, 4 drives configured in RAID5/6 array
- SATA-PCIe card: Silicon Image 3132 (2x speed) or Silicon Image 3124 (1x speed)

Software Platform Identification: Host development System Software

- QorIQ SDK 2.0 Release
- Compiler from QorIQ SDK 2.0

How to compile the kernel

If the distributed binary image in the ISO does not meet your requirement and you want to compile the kernel yourself, please make sure following kernel option is selected.

Table 615. Compiling kernel options

Kernel Configure Tree View Options	Description
[*] Enable the block layer ---> IO Schedulers ---> <*> Anticipatory I/O scheduler <*> Deadline I/O scheduler <*> CFQ I/O scheduler Default I/O scheduler (CFQ)	permit the block layer us to use correct I/O scheduler in the kernel

Table continues on the next page...

Table 615. Compiling kernel options (continued)

Kernel Configure Tree View Options	Description

Device Drivers --->
    <*> Serial ATA (prod) and Parallel ATA (experimental) drivers --->
     [*] Silicon Image 3124/3132 SATA support
     [*]   ATA SFF support
     <*>   Silicon Image SATA support
	Enable Silicon Image SATA driver

Device Drivers --->
    SCSI device support --->   [*] legacy /proc/scsi/ support
        --- SCSI support type (disk, tape, CD-ROM)
        <*> SCSI disk support
        <*> SCSI tape support
        <*> SCSI CDROM support
        [*]   Enable vendor-specific extensions (for SCSI CDROM)
        <*> SCSI generic support
   SCSI Transports --->   <*> Parallel SCSI (SPI) Transport Attributes
        [*] SCSI low-level drivers --->
	Enable SCSI disk, tape and CD-ROM support

[*] Multiple devices driver support (RAID and LVM) ---> --- Multiple devices driver support (RAID and LVM) <*> RAID support <*> Linear (append) mode <*> RAID-0 (striping) mode <*> RAID-1 (mirroring) mode <*> RAID-4/RAID-5/RAID-6 mode	Enable RAID support
Device Drivers ---> [*] DMA Engine support ---> [*] Freescale Elo and Elo Plus DMA support [*] Async_tx: Offload support for the async_tx api [*] Cryptographic API ---> --- Cryptographic API [*] Hardware crypto devices ---> --- Hardware crypto devices **For SEC3.x** <*> Talitos Freescale Security Engine (SEC) **For P5020/P5040** Device Drivers ---> [*] DMA Engine support ---> [*] Freescale RAID Engine Device Driver [*] Async_tx: Offload support for the async_tx api	**Important Note: As you know, different processors are equipped with different offloading capability. When you want to use the offload engine to offload the XOR calculation, you should know which hardware component is doing the offloading work and enable the corresponding kernel option. The guide lies below: SEC3.x: enable Talitos. P5020/P5040: enable RAID engine.**

12.2.10.3 Test Procedure

Hardware setup

Four SATA disks will be needed for a RAID system. You can compose a RAID array with two PCIe-SATA adaptors. Please connect the board, PCIe-SATA adaptor, and SATA disks as shown in figure 1. Here is an example.

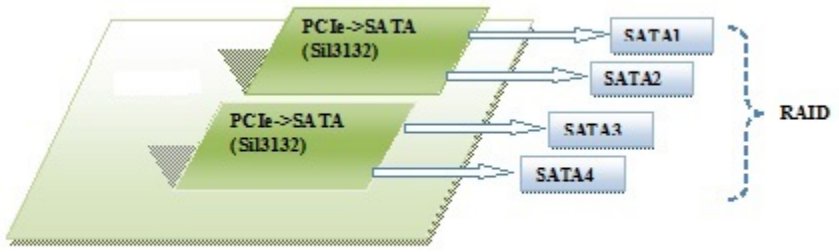

Figure 418. SATA connection for a RAID array

RAID setup

1. Create partitions for RAID

```
# fdisk /dev/sda
```

The number of cylinders for this disk is set to 19457. There is nothing wrong with that, but this is larger than 1024, and could in certain setups cause problems with:

- software that runs at boot time (e.g., old versions of LILO)
- booting and partitioning software from other OSs (e.g., DOS FDISK, OS/2 FDISK)

```
Command (m for help):___
   -  Enter "n"
Command action
   e   extended
   p   primary partition (1-4)
   -  Enter "p"
First cylinder (1-19457, 1): "1"
Last cylinder or +size or +sizeM or +sizeK (default 19457): "+4000M"
Change the Type of partition to Linux raid autodetect.
Command (m for help):___
   Enter "t"
Partition number (1-4): "1"
Hex code (type L to list codes):"fd"
Command (m for help): "w"
The partition table has been altered!
With the same procedures make other three partitions sdb1, sdc1 and sdd1
After creating all four partitions Log should be,
# fdisk -l
Disk /dev/sda: 160.0 GB, 160041885696 bytes
255 heads, 63 sectors/track, 19457 cylinders
Units = cylinders of 16065 * 512 = 8225280 bytes
   Device Boot    Start       End    Blocks   Id  System
/dev/sda1               1         487     3911796   fd  Linux raid autodetect
Disk /dev/sdb: 160.0 GB, 160041885696 bytes
```

```
255 heads, 63 sectors/track, 19457 cylinders
Units = cylinders of 16065 * 512 = 8225280 bytes
   Device Boot    Start       End    Blocks   Id  System
/dev/sdb1               1         487     3911796   fd  Linux raid autodetect
Disk /dev/sdc: 160.0 GB, 160041885696 bytes
255 heads, 63 sectors/track, 19457 cylinders
Units = cylinders of 16065 * 512 = 8225280 bytes
   Device Boot    Start       End    Blocks   Id  System
/dev/sdc1               1         487     3911796   fd  Linux raid autodetect
Disk /dev/sdd: 160.0 GB, 160041885696 bytes
255 heads, 63 sectors/track, 19457 cylinders
Units = cylinders of 16065 * 512 = 8225280 bytes
   Device Boot    Start       End    Blocks   Id  System
/dev/sdd1               1         487     3911796   fd  Linux raid autodetect
```

2. Create RAID array with Linux raid partition

```
# mdadm --create --verbose /dev/md0 --level=raid5 --raid-devices=4 /dev/sda1 /dev/sdb1 /dev/
sdc1 /dev/sdd1
md: bind<sda1>
md: bind<sdb1>
md: bind<sdc1>
md: bind<sdd1>
raid5: device sdc1 operational as raid disk 2
raid5: device sdb1 operational as raid disk 1
raid5: device sda1 operational as raid disk 0
raid5: allocated 4203kB for md0
raid5: raid level 5 set md0 active with 3 out of 4 devices, algorithm 2
RAID5 conf printout:
 --- rd:4 wd:3
 disk 0, o:1, dev:sda1
 disk 1, o:1, dev:sdb1
 disk 2, o:1, dev:sdc1
RAID5 conf printout:
 --- rd:4 wd:3
 disk 0, o:1, dev:sda1
 disk 1, o:1, dev:sdb1
 disk 2, o:1, dev:sdc1
 disk 3, o:1, dev:sdd1
mdadm: array /demd: recovery of RAID array md0
md: minimum _guaranteed_  speed: 1000 KB/sec/disk.
md: using maximum available idle IO bandwidth (but not more than 200000 KB/sec) for recovery.
md: using 128k window, over a total of 3911680 blocks.
dev/md0 started.

If want to create RAID6, please specify –level=raid6

Progress of the RAID array can be seen by,
# cat /proc/mdstat
Personalities : [raid6] [raid5] [raid4]
md0 : active raid5 sdd1[4] sdc1[2] sdb1[1] sda1[0]
      11735040 blocks level 5, 64k chunk, algorithm 2 [4/3] [UUU_]
      [==========>.........]  recovery = 52.7% (2065152/3911680) finish=0.9min speed=32080K/sec
Once recovery is completed RAID array is ready for data transfer.
```

3. Create File system on the RAID array and mount it

```
# mkfs.ext4 /dev/md0
# mount -o oldalloc,data=writeback,barrier=0,delalloc /dev/md0 /mnt
```

4. Tuning disk readahead and RAID stripe cache size

```
# echo 512 > /sys/block/sda/bdi/read_ahead_kb
# echo 512 > /sys/block/sdb/bdi/read_ahead_kb
# echo 512 > /sys/block/sdc/bdi/read_ahead_kb
# echo 512 > /sys/block/sdd/bdi/read_ahead_kb
# echo 1024 >/sys/block/md0/md/stripe_cache_size
```

Benchmarking and result explanation

1. Benchmarking RAID performance with iozone

```
# iozone -Rab result_file -i0 -i1 -n32M -g4G -r64 -f /mnt/test
```

Where,

- i stands for the kind of I/O to be run and values 0 and 1 means write and read respectively
- n and g represents the file sizes for the I/O
- r is the record size which will be used to the I/O's throughput
- f means the file on which I/O's will be performed

Here 4G is an example; it should be 2X RAM size.

2. Reading result

After iozone command is completed without error, there should be output such as the following table:

```
          32768      64  422159  703085   764872   766146

          65536      64  421909  703682   780245   781969

         131072      64  327741  432575   781069   781763

         262144      64  213168  254712   771225   773137

         524288      64  191111  201107   772176   774159

        1048576      64  170138  180182   771197   772426

        2097152      64  164549  160689   321871   324975

        4194304      64  156162  154649   307762   309286
```

This table shows write/rewrite/read/reread performance of different file sizes, from 32M to 4G. As the red text in the table, the write performance result is 152MB/s=156162/1024, read performance result is 300MB/s.

12.3 USDPAA

USDPAA - Benchmark Reproducibility Guides

12.3.1 Reflector

Details for reproducing USDPAA Refelctor performance results.

12.3.1.1 Introduction

This document describes the steps to verify performance of USDPAA Reflector.

12.3.1.2 Platform Identification

Hardware Platform Identification

Depending on the platform, the application uses the setup shown in the table below.

Table 616. System Setup

Platform	Platform Rev.	Silicon Rev.	Default frequency Core/CCB/DDR/ FMan	SerDes Protocol	Config. Name
B4860QDS	Rev B2	Rev 2.2	• CPU - 1600 MHz • CCB - 667 MHz • DDR - 933 MHz • FMan - 667 MHz	`0x2A_0x8D`	`N_RSSS_0x2A_ 0x8D`

12.3.1.3 Applications and Traffic Flow

USDPAA Reflector Applications

The USDPAA package provides 2 reflector applications:

- reflector
- hello_reflector

The table below provides a brief description for each reflector application.

Table 618. USDPAA Reflector Applications

Applications	Description
USDPAA PPAC reflector application	USDPAA reflector is implemented based on PPAC software framework. Please refer to USDPAA Reflector and PPAC User Guide for details.
USDPAA hello_reflector Application	USDPAA hello_reflector is a stand-alone application. It is a simplified implementation of reflector.

Reflector traffic flow

The reflector application swaps the source and destination MAC addresses of the received packet, swaps the IPv4 source and destination addresses of the received packet, and then sends the packet back out the same interface on which the packet was received.

On P2041RBD/P3041DS/P5020DS/LS1046ARDB, 14G reflecting is supported

On P4080DS, 22G reflecting is supported

On P5040DS, 26G reflecting is supported

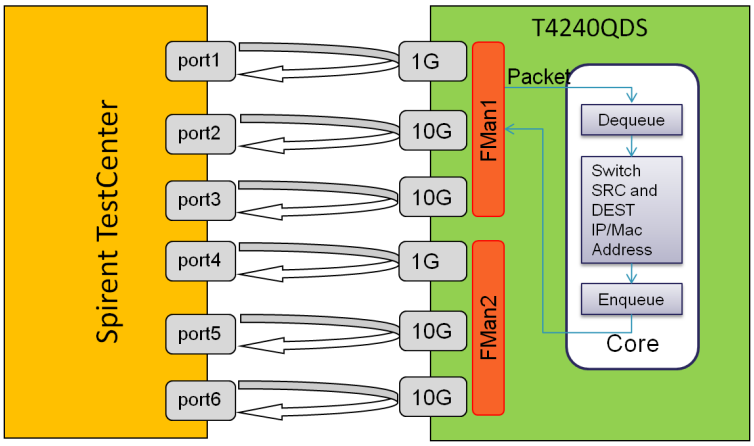
On B4860QDS, 20G reflecting is supported

On T4240QDS, 42G reflecting is supported

On T2080QDS, 24G reflecting is supported

On T1040RDB, 8G reflecting is supported

On LS1043ARDB, 6G reflecting is supported



DPAA Resource Configuration for Reflector

The configuration for DPAA blocks is critical to system performance. The Reflector application works with the following configuration:

Table 619. DPAA Resource Configuration for USDPAA Reflector

DPAA Resource	USDPAA IPv4 Forward Function

FMan	• Parsing on 32 bytes parser: result comes with every frame.
	  • Protocol parsing
	  • IP Header location
	  • IP Header checksum check
	  • Error code
	• Congestion management disabled. Fman side order restoration is on.
	• Hash is based on the SIP,DIP

QMan	• Push mode, Triple dequeue enable.
	• DQRR:
	  • Entry Stashing on.
	  • To L1 cache, with high priority.
	• Frame data, Annotation, Context stashing on: –Frame data = 1 line, Annotation = 1 line, Context = 1
	• Consumer Index write mode cache-inhibited: Update on every 3 frames dequeue.
	• EQRR: Access through Cache Enable Access (CENA, WIMGE=00000)

BMan	• Buffer Pool: bp9 • Buffer Size: 1728 Bytes • Number of buffers: 8192
DMA Memory	• 256MB for 32 bit platform • 256MB for 64 bit platform

12.3.1.4 Test Procedure

Steps for PPAC reflector application

The following instructions are specifically for the Spirent TestCenter, though other traffic generators can also be used.

Step 1: Configure FMan PCD:

- Login to the target
- Configure FMan with fmc:

```
# cd /usr/etc
# fmc -c <fmc_config> -p usdpaa_policy_hash_ipv4.xml –a
```

Please note that <fmc_config> can be one of the following:

Table 620. fmc Configuration

Platform	fmc_config file
B4860QDS	usdpaa_config_b4_serdes_0x2a_0x98.xml
P2041RDB/P3041DS/P5020DS	usdpaa_config_p2_p3_p5_14g.xml
P4080DS	usdpaa_config_p4_serdes_0xe.xml
P5040DS	usdpaa_config_p5_serdes_0x02.xml
T4240QDS	usdpaa_config_t4_serdes_1_1_5_5.xml
T4240RDB	usdpaa_config_t4_48g.xml
T2080QDS	usdpaa_config_t2_serdes_66_15.xml
T1024RDB	usdpaa_config_t1024_serdes_0x99.xml
T1040RDB	usdpaa_config_t1_serdes_0x66.xml
LS1043ARDB	usdpaa_config_ls1043.xml
LS1046ARDB	usdpaa_config_ls1046.xml

Step 2 (For T1040RDB only): Configure the L2switch FDB entries:

```
# killall l2sw_bin
# l2sw_bin
l2switch> mac add 00:11:22:33:44:01 0                  (Add mac address to FDB of port 0)
l2switch> mac add 00:11:22:33:55:01 1
l2switch> mac add 00:11:22:33:44:02 2
l2switch> mac add 00:11:22:33:55:02 3
l2switch> mac add 00:11:22:33:44:03 4
l2switch> mac add 00:11:22:33:55:03 4
l2switch> mac add <mac addr of fm1-gb0> 8
l2switch> mac add <mac addr of fm1-gb1> 9
l2switch> mac dump

Type VID MAC Address Ports
------ --- ----------------- -----
Static  1    00:11:22:33:44:01  0
Static  1    00:11:22:33:44:02  2
Static  1    00:11:22:33:44:03  4
Static  1    00:11:22:33:55:01  1
Static  1    00:11:22:33:55:02  3
Static  1    00:11:22:33:55:03  4
Static  1    00:e0:0c:00:31:00  8
Static  1    00:e0:0c:00:31:01  9

Static  entries: 8
Dynamic entries: 0
l2switch> Ctrl+C                                    (To terminate process without cleaning up
L2switch setting)
```

Reflector on T1040RDB is a special case because it involves L2 switch which has eight 1G front ports and is internally connected with DPAA through two 2.5G ports (fm1-gb0 & fm1-gb1). In order to achieve maximum throughput of DPAA, we have to send traffic to fm1-gb0/1 through port 0-4 of L2switch.

The Destination Mac address of packets that are sent to fm1-gb0 should be Mac address of fm1-gb0; the Source Mac address that are sent out from port 0 of L2switch should be 00:11:22:33:44:01 which we have already added into FDB of port 0 in step 3.

Step 3: Launch reflector application

```
# reflector <cpu_range> -c <fmc_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000
```

NOTE

<cpu_range> could be a single core number, like 1, 2, or a range, like 1..8, 0..23 etc. <fmc_config> should be the same file used in Step 2.

On T2080QDS, user could get better performance with 8 cores if user adds parameter '-s' for reflector.

e.g. reflector 0..7 –c usdpaa_config_t2_serdes_66_15.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000 -s

Step 4: Configure Spirent TestCenter project.

Create Command Sequencer in TestCenter and select RFC2544 Throughput test. Then set Test Parameters for TestCenter Throughput Sequencer as shown in table below.

Table 621. Spirent TestCenter Throughput Configuration

Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Initial rate	100%
Packet Loss Rate	0.001%
Packet Size	64, 390, 1024, 1518 bytes

OK
Cancel

Step 5: Now the PPAC reflector is ready to receive packet, Launch TestCenter project to start traffic

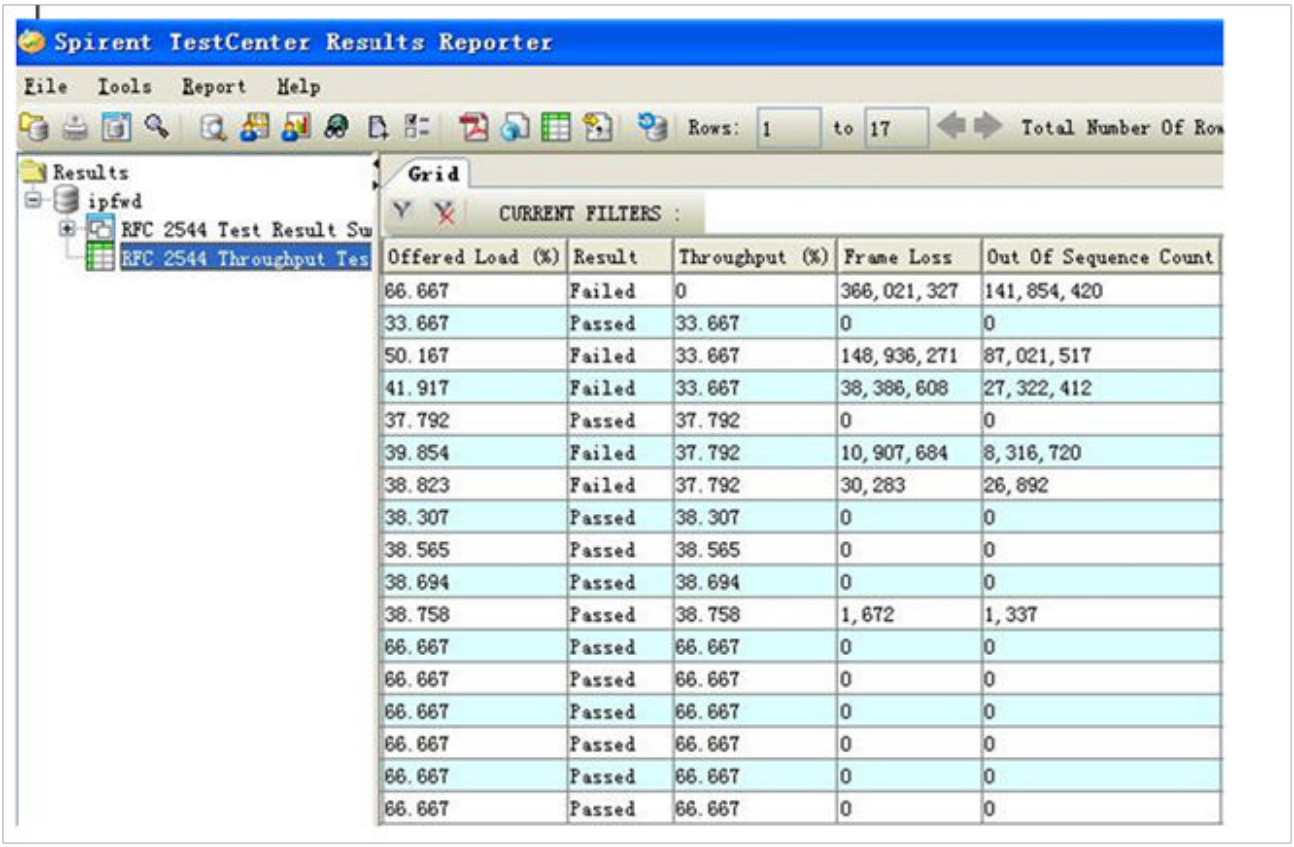
Steps for hello_reflector application

The steps for the hello_reflector application are the same as in PPAC reflector except for **Step 3**:

```
# hello_reflector -c <fmc_config> -p usdpaa_policy_hash_ipv4.xml -n <number of threads>
```

12.3.1.5 View of Test Results

When measuring performance using TestCenter RFC 2544 Command Sequence, the result summary can be viewed using the Spirent TestCenter Results Reporter. To prevent any "out of sequence" packets when measuring with Zero Loss Throughput, enable Order Preservation or Order Restoration.



Offered Load (%)	Result	Throughput (%)	Frame Loss	Out Of Sequence Count
66.667	Failed	0	366,021,327	141,854,420
33.667	Passed	33.667	0	0

NOTE

*For more information about boot arguments, refer to USDPAA Boot Arguments.

12.3.2.3 Applications and traffic flow

USDPAA applications for IPv4 forwarding

USDPAA RC-based IPFwd Application Suite

Route cache(RC) based IPFwd takes route decision based upon hash results calculated by FMAN using source IP address and destination IP address in the frame. It contains two applications:

- ipfwd_app: The application that takes charge of initializing devices, managing threads and buffers and packets processing
- ipfwd_config: The command line interface(CLI) to configure ipfwd, such as IP addresses assignment to each port, ip routes and ARP routes management, starting packets processing

USDPAA LPM IPFwd Application Suite

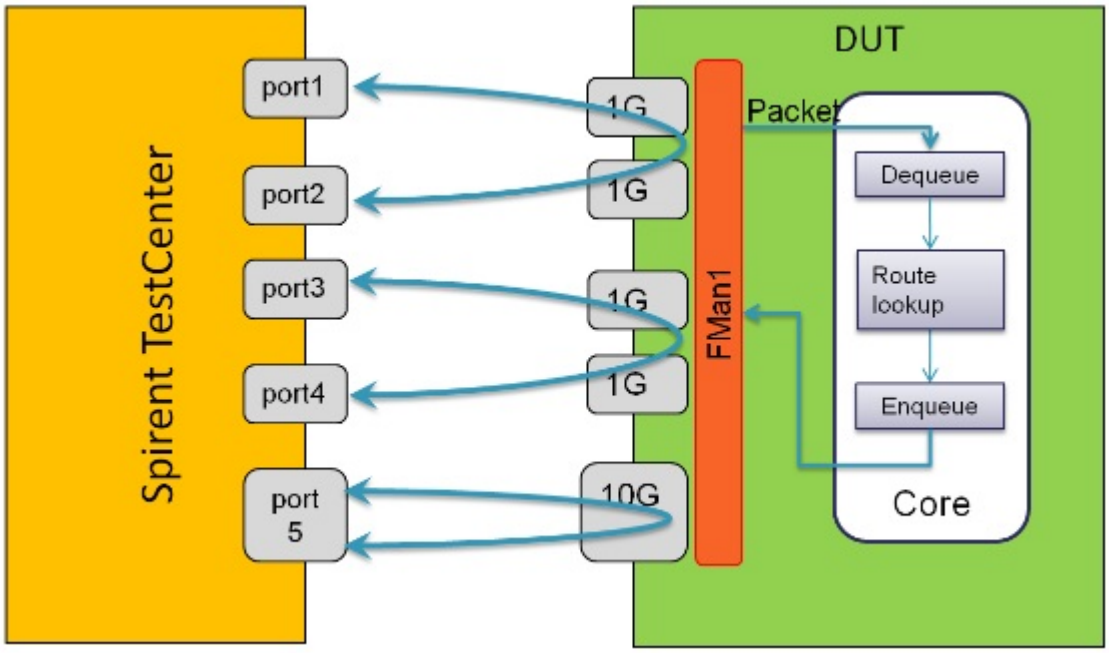
LPM-based IPFwd uses Longest Prefix Match algorithm for doing route lookup by using prefix for destination IP address. It contains two applications:

- lpm_ipfwd_app: The application that takes charge of initializing devices, managing threads and buffers and packets processing
- lpm_ipfwd_config: The command line interface(CLI) to configure ipfwd, such as IP addresses assignment to each port, destination routes and ARP routes management, starting packets processing

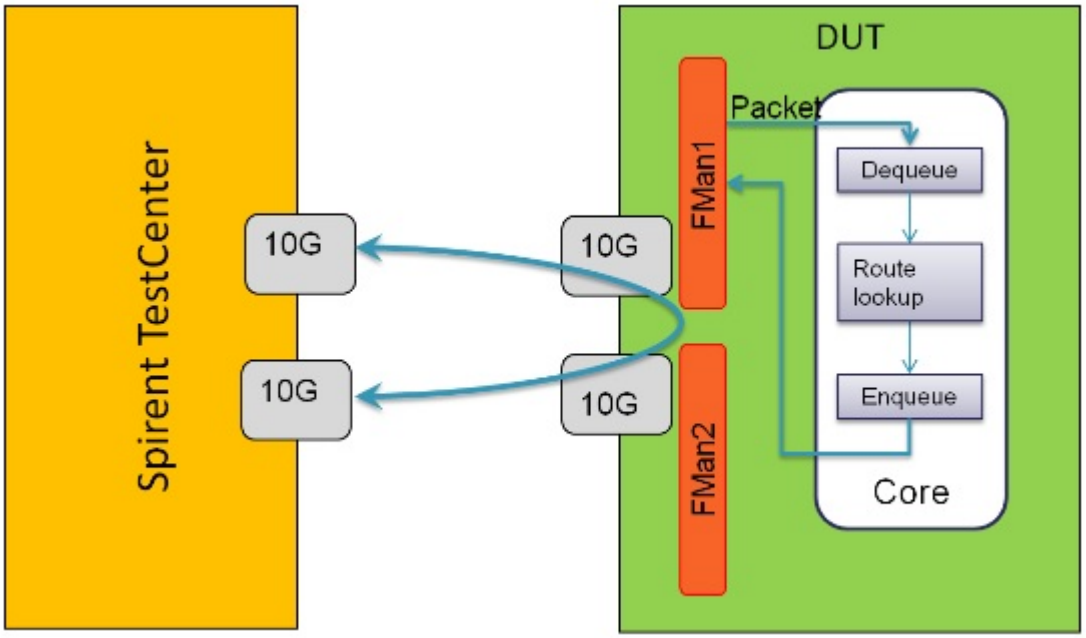
IP forwarding working flow

IP forwarding working flow varies on different platforms.

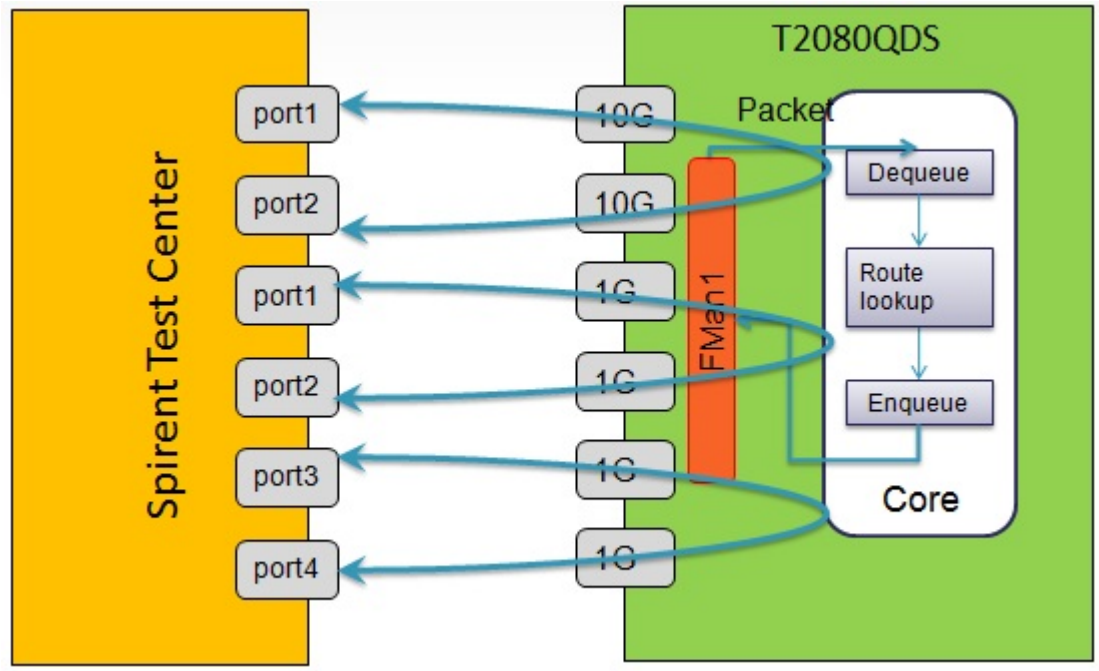
For P2041RBD/P3041DS/P5020DS/LS1046ARDB, they support 14G IP forwarding:



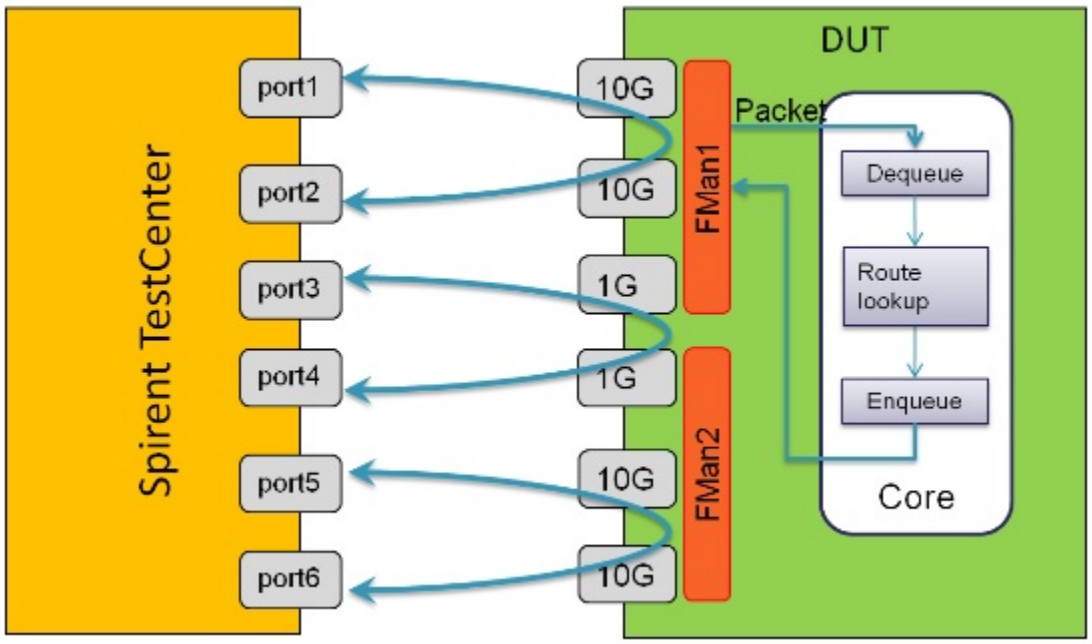
For P4080DS/P5040DS/B4860QDS, they support 20G IP forwarding: B4860QDS has two 10G ports on single FMan.



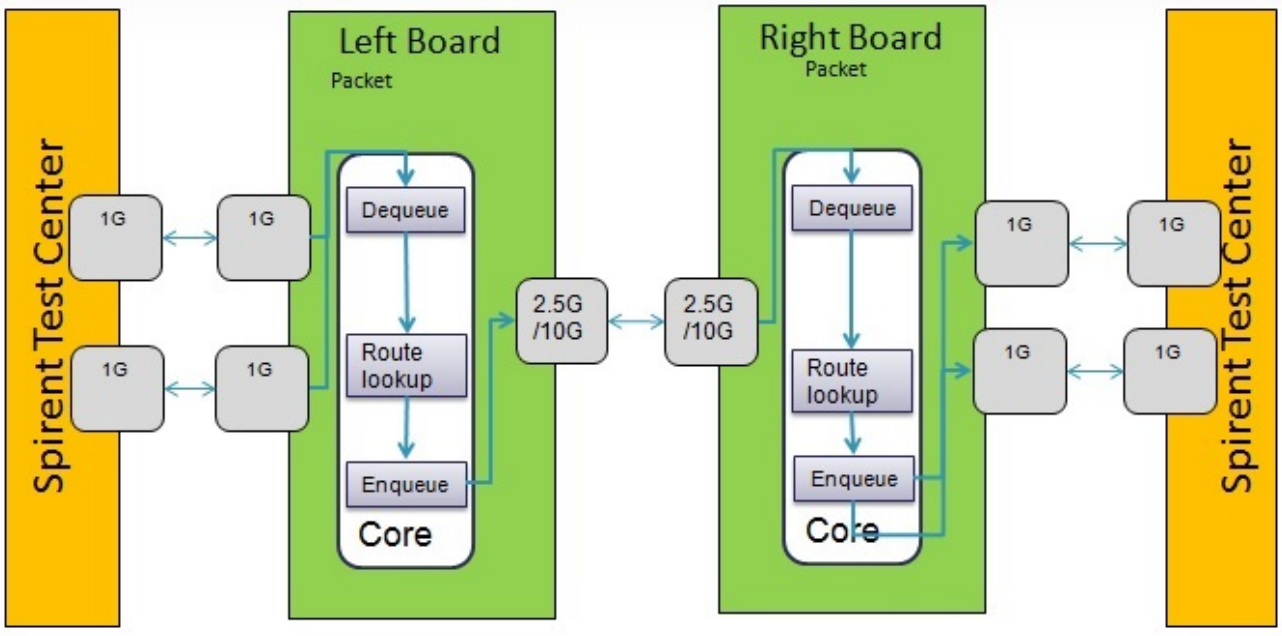
For T2080QDS, they support 24G IP forwarding:



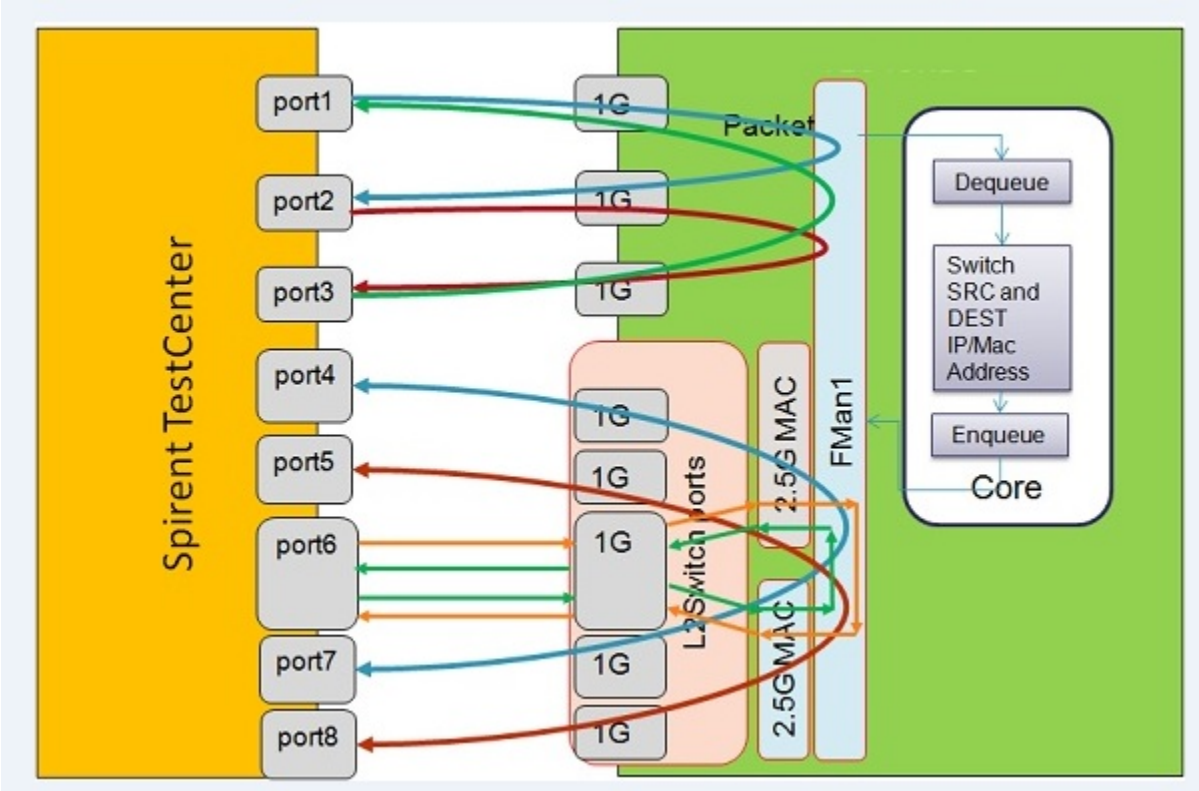
For T4240QDS, it supports 42G IP forwarding:



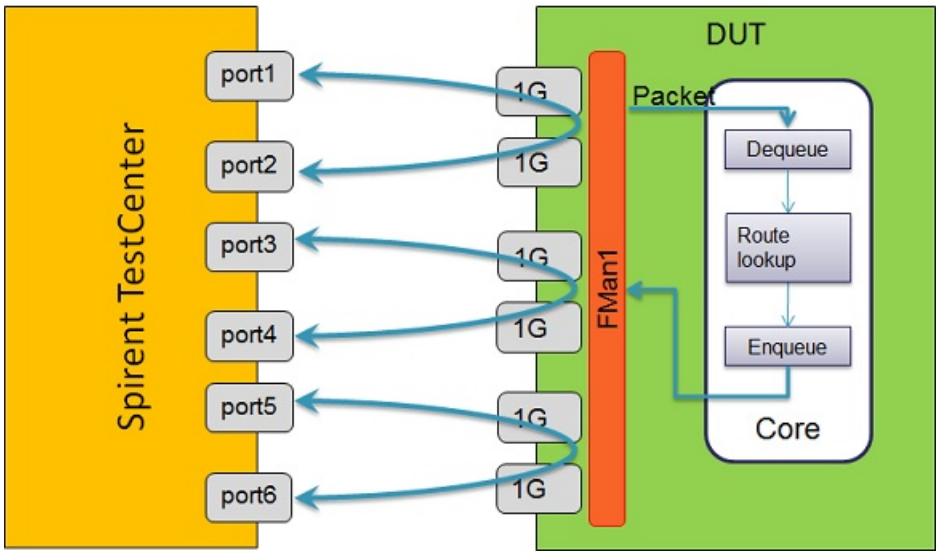
For T1023RDB/T1024RDB, it supports 4G IP forwarding:



For T1040D4RDB, it supports 8G IP forwarding, but traffic flow looks much more complex because there are five 1G MACs on the L2 switch used for traffic transmission:



For LS1043ARDB, it supports 6G IP forwarding



DPAA resource configuration for IPv4 forwarding

Table 624. DPAA resource configuration for USDPAA IP forwarding

DPAA Resource	USDPAA IPv4 Forward Function

FMan	• Parsing on : 32 bytes parser result comes with every frame, such as:
	  • Protocol parsing
	  • IP Header location
	  • IP Header checksum check
	  • Error code
	• Congestion management disabled. Fman side order restoration is on.
	• Hash is based on the SIP,DIP

QMan	• Push mode, Triple dequeue enable.
	• DQRR:
	  • Entry Stashing on.
	  • To L1 cache, with high priority.
	• Frame data, Annotation, Context stashing on: –Frame data = 1 line, Annotation = 1 line, Context = 1
	• Consumer Index write mode cache-inhibited: Update on every 3 frames dequeue.
	• EQRR: Access through Cache Enable Access (CENA, WIMGE=00000)

BMan	• Buffer Pool: bp9 • Buffer Size: 1728 Bytes • Number of buffers: 2048
DMA Memory	• 256MB for 32 bit platform • 256MB for 64 bit platform

12.3.2.4 RC-ipfwd for P2041RDB/P3041DS/P5020DS

Procedure for RC-ipfwd application

1. Boot board with usdpaa mode, then execute commands on board:

Table 625. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	`# ifconfig eth0 192.168.1.200`	set ethernet port IP addr.
b	---	`# cd /usr/etc`	---

Table continues on the next page...

Table 625. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes

c	Configure PCD	`# fmc -c usdpaa_config_p2_p3_p5_14g.xml -p usdpaa_policy_hash_ipv4.xml -a`
		`# fmc -c usdpaa_config_ls1046.xml -p usdpaa_policy_hash_ipv4.xml -a`
		`(For LS1046ARDB)`	

d	Launch IP forward application which creates one thread on core 1 & 2 individually	`# ipfwd_app 0..1 -c usdpaa_config_p2_p3_p5_14g.xml -p usdpaa_policy_hash_ipv4.xml -d 0x10000000` `# ipfwd_app 0..1 -c usdpaa_config_ls1046.xml -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	`ssh root@192.168.1.200`	---
f	Run IP forwarding configuration script in ssh session	`# ipfwd_14G.sh $PID`	PID is the process id of ipfwd_app. It is printed when ipfwd_app starts
g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready to receive traffic

2. Open TestCenter project and reserve ports. Then create ‘Raw Stream’ in generator for each port, and compose packet as follows (change Mac/IP address, count number according to your environment):

Port 2 to Port 1	196	192.168.20.2 –-- 192.168.20.15	192.168.10.2 –-- 192.168.10.15
Port 3 to Port 4	196	192.168.40.2 –-- 192.168.40.15	192.168.50.2 –-- 192.168.50.15
Port 4 to Port 3	196	192.168.50.2 –-- 192.168.50.15	192.168.40.2 –-- 192.168.40.15
Port 5 to Port 5	196	192.168.60.2 –-- 192.168.60.15	192.168.60.2 –-- 192.168.60.15
Total # Flows =	980	n/a	n/a

3. Create Command Sequencer in TestCenter and select RFC2544 Throughput template. Then set options as shown in the following table:

Table 627. Command Sequencer configuration

Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Packet Loss Rate	0.001%
Packet Size	64, 128, 256, 512, 1024, 1280, 1518 bytes

4. Start TestCenter Command Sequencer to measure performance.

12.3.2.5 RC-ipfwd for P4080DS/P5040DS/B4860QDS

Procedure for RC-ipfwd application

1. Boot board with usdpaa mode, then execute commands on board:

Table 628. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	`# ifconfig eth0 192.168.1.200`	set ethernet port IP addr.
b	---	`# cd /usr/etc`	---

Table continues on the next page...

Table 628. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
c	Configure PCD	`# fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	xml policy file can be found in file system. <fman_config> is: for P4080DS usdpaa_config_p4_serdes_0xe.xml; P5040DS usdpaa_config_p5_serdes_0x02.xml; B4860QDS usdpaa_config_b4_serdes_0x2a_0x98.xml; T2080QDS usdpaa_config_t2_serdes_66_16_22g.xml
d	Launch IP forward application which creates one thread on core 1 & 2 individually	`# ipfwd_app 1..2 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports.
e	Login Linux from tftp server	`ssh root@192.168.1.200`	---
f	Run IP forward configuration script in ssh session	`# ipfwd_20G.sh $PID`	PID is the process id of ipfwd_app and it is printed when the application starts
g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *RC-ipfwd for P4080DS/P5040DS/B4860QDS*, except IP address assignments.

Table 629. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	506	192.168.60.2 –-- 192.168.60.23	192.168.160.2 –-- 192.168.160.24
Port 2 to Port 1	506	192.168.160.2 –-- 192.168.160.23	192.168.60.2 –-- 192.168.60.24
Total # Flows =	1012	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.6 RC-ipfwd for T2080QDS

Procedure for LPM-ipfwd application

1. Create a Shell script 'ipfwd_24G.sh' with following content:

```
pid=$1
   pid=$1
```

```
board_type=$(uname -n)
if [ "$pid" == "" ]
        then
                echo "Give PID to hook up with"
                exit 1
fi

net_pair_routes()
{
        for net in $1 $2
        do
                ipfwd_config -P $pid -B -s 192.168.$net.2 -c $3 \
                -d 192.168.$(expr $1 + $2 - $net).2 -n $4 -g \
                192.168.$(expr $1 + $2 - $net).2
        done
}

ipfwd_config -P $pid -F -a 192.168.0.1 -i 1
ipfwd_config -P $pid -F -a 192.168.1.1 -i 2
ipfwd_config -P $pid -F -a 192.168.2.1 -i 3
ipfwd_config -P $pid -F -a 192.168.3.1 -i 4
ipfwd_config -P $pid -F -a 192.168.8.1 -i 89
ipfwd_config -P $pid -F -a 192.168.9.1 -i 90

ipfwd_config -P $pid -G -s 192.168.0.2 -m 0F:11:22:33:44:00 -r true
ipfwd_config -P $pid -G -s 192.168.1.2 -m 0F:11:22:33:44:01 -r true
ipfwd_config -P $pid -G -s 192.168.2.2 -m 0F:11:22:33:44:02 -r true
ipfwd_config -P $pid -G -s 192.168.3.2 -m 0F:11:22:33:44:03 -r true
ipfwd_config -P $pid -G -s 192.168.8.2 -m 0F:11:22:33:44:08 -r true
ipfwd_config -P $pid -G -s 192.168.9.2 -m 0F:11:22:33:44:09 -r true

                                # 1014
net_pair_routes 0 1 13 13     # 2 * 13 * 13
net_pair_routes 2 3 13 13     # 2 * 13 * 13
net_pair_routes 8 9 13 13     # 2 * 13 * 13
echo IPFwd Route Creation completed
```

2. Boot board with USDPAA mode, then execute the following commands on the board:

Table 630. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c <fman_config> –p usdpaa_policy_hash_ipv4.xml –a	xml policy file can be found in file system. <fman_config> here is: usdpaa_config_t2_serdes_66_15.xml for T2080QDS

Table continues on the next page...

Table 630. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#ipfwd_app 1..3 -c <fman_config> –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports. On T2080QDS, user could get better performance with 8 cores if user adds parameter '-s' for ipfwd_app. e.g. ipfwd_app 0..7 -c usdpaa_config_t2_serdes_66_16_22g.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000
e	Login Linux from tftp server	ssh root@192.168.1.200	---
f	Run IP forward configuration script in ssh session	#ipfwd_24G.sh $PID	PID is the process id of lpm_ipfwd. It is printed when ipfwd starts
g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

3. Refer to Step 2 & 3 in the section, *RC-ipfwd for T2080QDS*, except IP address assignments.

Table 631. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	169	192.168.0.2 – 192.168.0.14	192.168.01.2 – 192.168.01.14
Port 2 to Port 1	169	192.168.1.2 – 192.168.1.14	192.168.0.2 – 192.168.0.14
Port 3 to Port 4	169	192.168.2.2 – 192.168.2.14	192.168.3.2 – 192.168.3.14
Port 4 to Port 3	169	192.168.3.2 – 192.168.3.14	192.168.2.2 – 192.168.2.14
Port 10G 1 to Port 10G 2	169	192.168.8.2 – 192.168.8.14	192.168.9.2 – 192.168.9.14
Port 10G 2 to Port 10G 1	169	192.168.9.2 – 192.168.9.14	192.168.8.2 – 192.168.8.14
Total # Flows =	1014	n/a	n/a

4. Start TestCenter Command Sequencer to measure performance.

12.3.2.7 RC-ipfwd for T4240QDS/T4240RDB

Procedure for RC-ipfwd application

1. Boot board with USDPAA mode, then execute the following commands on the board:

Table 632. Operations on Board

Step	Action	Command on Linux Partition	Notes
a	---	`# ifconfig eth0 192.168.1.200`	set ethernet port IP addr.
b	---	`# cd /usr/etc`	---
c	Configure PCD	`# fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	<fman_config> for T4240QDS is usdpaa_config_t4_serdes_1_1_5_5.xml, for T4240RDB is usdpaa_config_t4_48g.xml
d	Launch IP forward application which creates one thread on each core	`# ipfwd_app 0..23 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	`ssh root@192.168.1.200`	---
f	Modify IP forwarding configuration script for T4240RDB	sed -i 's/-i 5/-i 1/;s/-i 105/-i 101/' /usr/bin/ipfwd_42G.sh	Ignore this step if you are using T4240QDS
g	Run IP forwarding configuration script in ssh session	`# ipfwd_42G.sh $PID`	PID is the process id of ipfwd_app and it is printed when the application starts
h	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *RC-ipfwd for P2041RDB/P3041DS/P5020DS*, except IP address assignments.

Table 633. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	225	192.168.50.2 – 192.168.50.16	192.168.60.2 – 192.168.60.16
Port 2 to Port 1	225	192.168.60.2 – 192.168.60.16	192.168.50.2 – 192.168.50.16
Port 3 to Port 4	49	192.168.40.2 – 192.168.40.8	192.168.130.2 – 192.168.130.8
Port 4 to Port 3	49	192.168.130.2 – 192.168.130.8	192.168.40.2 – 192.168.40.8
Port 5 to Port 6	225	192.168.140.2 – 192.168.140.16	192.168.150.2 – 192.168.150.16

Table continues on the next page...

Table 633. IP addresses assignment (continued)

Packet Flow	Number of Flows	Source Values	Destination Values
Port 6 to Port 5	225	192.168.150.2 – 192.168.150.16	192.168.140.2 – 192.168.140.16
Total # Flows =	998	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.8 RC-ipfwd for T1023RDB/T1024RDB

Procedure for RC-ipfwd application

1. Boot two board with usdpaa mode, then execute commands on each board:

Table 634. Operations on board

Step	Action	Command on Linux Partition	Notes
a	Config ethernet port	`# ifconfig eth0 192.168.1.200`	set ethernet port IP addr.
b	Get into PCD file folder	`# cd /usr/etc`	---
c	Configure PCD	`# fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	xml policy file can be found in file system <fman_config> is: T1023RDB: usdpaa_config_t1023_serdes_0x77.xml T1024RDB: usdpaa_config_t1024_serdes_0x99.xml
d	Launch IP forward application which creates one thread on each core	`# ipfwd_app 0..1 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	`ssh root@192.168.1.200`	---

Table continues on the next page...

Table 634. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes

f	Run IP forward configuration script in ssh session	`# cd /usr/bin`
		`# T1023RDB`
		`# sed -i 's/00:04:9f: 01:02:05/00:e0:0c:00:76:02/g' ipfwd_t1023_4.5G.sh`
		`# sed -i 's/00:04:9f: 11:12:24/00:e0:0c:00:4A:02/g' ipfwd_t1023_4.5G.sh`
		`# ipfwd_t1023_4.5G.sh $PID`
		`# T1024RDB`
		`# sed -i 's/00:04:9f: 01:02:05/00:e0:0c:00:6F:00/g' ipfwd_t1024_12G.sh`
		`# sed -i 's/00:04:9f: 11:12:24/00:e0:0c:00:71:00/g' ipfwd_t1024_12G.sh`
		`# ipfwd_t1024_12G.sh $PID`
			PID is the process id of ipfwd_app and it is printed when the application starts

g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *RC-ipfwd for T1023RDB/T1024RDB*, except IP address assignments.

Table 635. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Board 1 Port 1 to board 2 Port 1	256	192.168.20.2 – 192.168.20.17	192.168.40.2 – 192.168.40.17
Board 2 Port 1 to board 1 Port 1	256	192.168.40.2 – 192.168.40.17	192.168.20.2 – 192.168.20.17
Board 1 Port 2 to Board 2 Port 2	256	192.168.30.2 – 192.168.30.17	192.168.50.2 – 192.168.50.17

Table continues on the next page...

Table 635. IP addresses assignment (continued)

Packet Flow	Number of Flows	Source Values	Destination Values
Board 2 Port 2 to board 1 Port 2	256	192.168.50.2 – 192.168.50.17	192.168.30.2 – 192.168.30.17
Total # Flows =	1024	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.9 RC-ipfwd for T1040D4RDB

Procedure for RC-ipfwd application

1. Configure FDB entries for L2 switch through application 'l2sw_bin'

```
# l2sw_bin
l2sw_bin> mac add static 00:11:22:33:44:01 0
l2sw_bin> mac add static 00:11:22:33:44:02 1
l2sw_bin> mac add static 00:11:22:33:44:03 2
l2sw_bin> mac add static 00:11:22:33:55:03 2
l2sw_bin> mac add static 00:11:22:33:55:01 3
l2sw_bin> mac add static 00:11:22:33:55:02 4
l2sw_bin> mac add static <fm1-gb0 mac> 8   # replace <...> with real MAC address
l2sw_bin> mac add static <fm1-gb1 mac> 9   # replace <...> with real MAC address
l2sw_bin> Press Ctrl+C to quit l2sw_bin application
```

2. Create a Shell script 'ipfwd_8g_t1040d4rdb.sh' with following content

```
pid=$1

net_pair_routes()
{
    if [ "x$5" == "x" ]
    then
        gwip=2
    else
        gwip=$5
    fi

    for net in $1 $2
    do
        ipfwd_config -P $pid -B -s 192.168.$net.2 -c $3 \
        -d 192.168.$(expr $1 + $2 - $net).$gwip -n $4 \
        -g 192.168.$(expr $1 + $2 - $net).$gwip
    done
}

net_directional_routes()
{
    ipfwd_config -P $pid -B -s 192.168.$1.2 -c $3 \
        -d 192.168.$2.2 -n $4 -g 192.168.$2.2
}

ipfwd_config -P $pid -F -a 192.168.10.1 -i 0
```

```
ipfwd_config -P $pid -F -a 192.168.20.1 -i 1
ipfwd_config -P $pid -F -a 192.168.30.1 -i 2
ipfwd_config -P $pid -F -a 192.168.40.1 -i 3
ipfwd_config -P $pid -F -a 192.168.50.1 -i 4

ipfwd_config -P $pid -G -s 192.168.10.2 -m 00:11:22:33:44:01 -r true
ipfwd_config -P $pid -G -s 192.168.10.8 -m 00:11:22:33:44:02 -r true
ipfwd_config -P $pid -G -s 192.168.10.14 -m 00:11:22:33:44:03 -r true
ipfwd_config -P $pid -G -s 192.168.20.2 -m 00:11:22:33:55:01 -r true
ipfwd_config -P $pid -G -s 192.168.20.8 -m 00:11:22:33:55:02 -r true
ipfwd_config -P $pid -G -s 192.168.20.14 -m 00:11:22:33:55:03 -r true
ipfwd_config -P $pid -G -s 192.168.30.2 -m 02:00:c0:a8:1e:02 -r true
ipfwd_config -P $pid -G -s 192.168.40.2 -m 02:00:c0:a8:28:02 -r true
ipfwd_config -P $pid -G -s 192.168.50.2 -m 02:00:c0:a8:32:02 -r true

# 1050 Flows
net_pair_routes 10 20 14 6 2        # 2 * 14 * 6 = 168
net_pair_routes 10 20 14 6 8        # 2 * 14 * 6 = 168
net_pair_routes 10 20 14 3 14       # 2 * 14 * 3 = 84
net_directional_routes 30 40 14 15  # 14 * 15 = 210
net_directional_routes 40 50 14 15  # 14 * 15 = 210
net_directional_routes 50 30 14 15  # 14 * 15 = 210

echo IPFwd Route Creation completed
```

3. Boot board with usdpaa mode, then execute commands on board:

Table 636. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	`# ifconfig eth0 192.168.1.200`	set ethernet port IP addr.
b	---	`# cd /usr/etc`	---
c	Configure PCD	`# fmc -c usdpaa_config_t1_serdes_0x66.xml -p usdpaa_policy_hash_ipv4.xml -a`	
d	Launch IP forward application which creates one thread on each core	`# ipfwd_app 0..23 -c usdpaa_config_t1_serdes_0x66.xml -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	`ssh root@192.168.1.200`	---
f	Run IP forward configuration script in ssh session	`# ipfwd_8g_t1040d4rdb.sh $PID`	PID is the process id of ipfwd_app and it is printed when the application starts
g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

4. Refer to Step 2 & 3 in the section, *RC-ipfwd for T1040D4RDB*, except IP address assignments.

Table 637. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	210	192.168.30.2 – 192.168.30.15	192.168.40.2 – 192.168.40.16
Port 2 to Port 3	210	192.168.40.2 – 192.168.40.15	192.168.50.2 – 192.168.50.16
Port 3 to Port 1	210	192.168.50.2 – 192.168.50.15	192.168.30.2 – 192.168.30.16
Port 4 to Port 7	84	192.168.10.2 – 192.168.10.15	192.168.20.2 – 192.168.20.7
Port 5 to Port 8	84	192.168.10.2 – 192.168.10.15	192.168.20.8 – 192.168.20.13
Port 6 to Port 6	84	Streamblock 1 192.168.10.2 – 192.168.10.15 Streamblock 2 192.168.20.2 – 192.168.20.15	Streamblock 1 192.168.20.14 – 192.168.20.16 Streamblock 2 192.168.10.14 – 192.168.10.16
Port 7 to Port 4	84	192.168.20.2 – 192.168.20.15	192.168.10.2 – 192.168.10.7
Port 8 to Port 5	84	192.168.20.2 – 192.168.20.15	192.168.10.8 – 192.168.10.13
Total # Flows =	1050	n/a	n/a

5. Start TestCenter Command Sequencer to measure performance.

12.3.2.10 RC-ipfwd for LS1043ARDB

Procedure for RC-ipfwd application

1. Boot board with usdpaa mode, then execute commands on board:

Table 638. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	`# ifconfig eth0 192.168.2.200`	set ethernet port IP addr.
b	---	`# cd /usr/etc`	---
c	Configure PCD	`#fmc -c usdpaa_config_ls1043.xml -p usdpaa_policy_hash_ipv4.xml -a`	xml policy file can be found in file system.

Table continues on the next page...

Table 638. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
d	Launch IP forward application which creates one thread on each core individually	`# ipfwd_app 0..3 -c usdpaa_config_ls1043.xml -p usdpaa_policy_hash_ipv4.xml`	You may use any combination of available cores the platform supports.
e	Login to board from tftp server	`ssh root@192.168.2.20`	---
f	Run IP forward configuration script in ssh session	`# ipfwd_ls1043a_6G.sh $PID`	PID is the process id of ipfwd_app and it is printed when the application starts
g	Launch TestCenter project to pump traffic	---	Now the ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *RC-ipfwd for P2041RDB/P3041DS/P5020DS*, except IP address assignments.

Table 639. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	169	192.168.10.2 -- 192.168.10.14	192.168.20.2 -- 192.168.20.14
Port 2 to Port 1	169	192.168.20.2 -- 192.168.20.14	192.168.10.2 -- 192.168.10.14
Port 3 to Port 4	169	192.168.30.2 -- 192.168.40.14	192.168.40.2 -- 192.168.30.14
Port 4 to Port 3	169	192.168.40.2 -- 192.168.30.14	192.168.30.2 -- 192.168.40.14
Port 5 to Port 6	169	192.168.50.2 -- 192.168.60.14	192.168.60.2 -- 192.168.50.14
Port 6 to Port 5	169	192.168.60.2 -- 192.168.50.14	192.168.50.2 -- 192.168.60.14
Total # Flows =	1014	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.11 LPM-ipfwd for P2041RDB/P3041DS/P5020DS

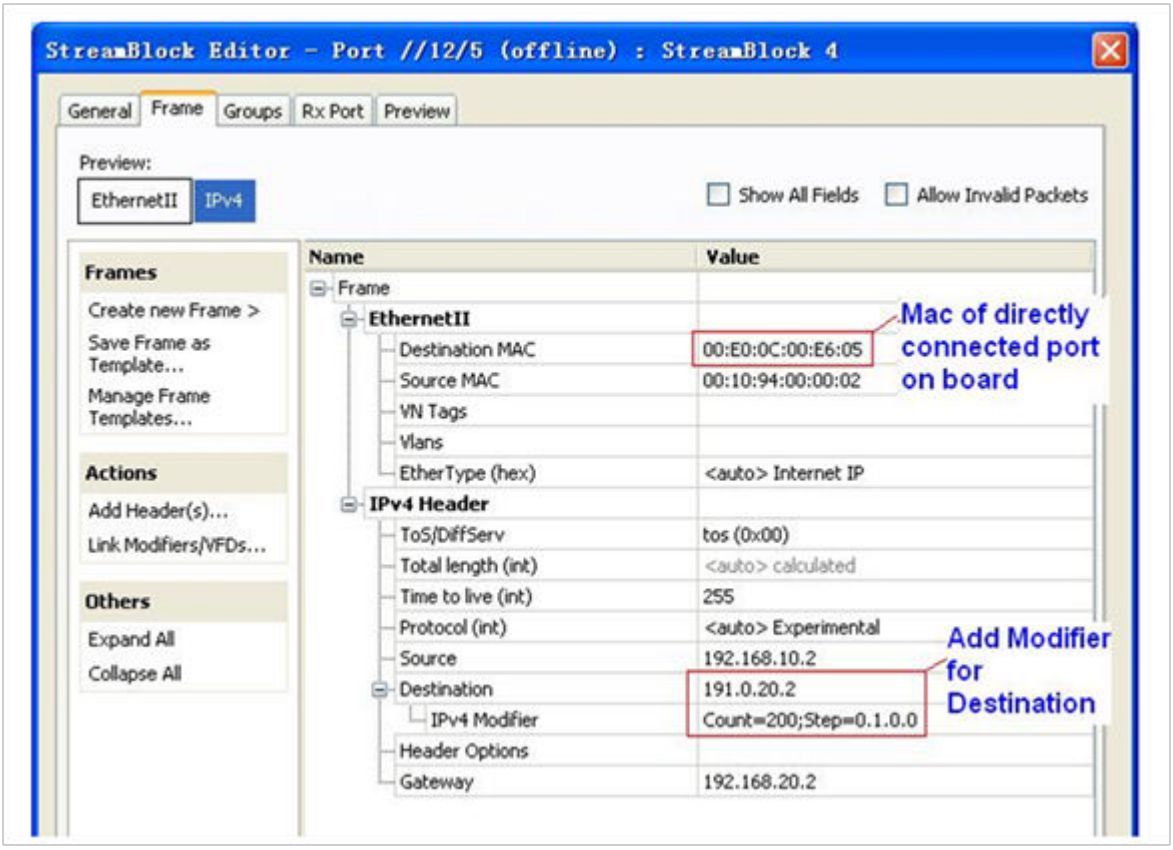
Procedure for LPM-ipfwd application

1. Boot board with usdpaa mode, then execute commands on board:

Table 640. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –a # fmc –c usdpaa_config_ls1046.xml –p usdpaa_policy_hash_ipv4.xml –a (For LS1046ARDB)	
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#lpm_ipfwd_app 1..3 -c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000 #lpm_ipfwd_app 1..3 -c usdpaa_config_ls1046.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	ssh root@192.168.1.200	---
f	Run IP forward configuration script in ssh session	#lpm_ipfwd_14G.sh $PID	PID is the process id of lpm_ipfwd_app. It is printed when lpm_ipfwd_app starts
g	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready to receive traffic

2. Open TestCenter project and reserve ports. Then create ‘Raw Stream’ in generator for each port, and compose packet as following: (change Mac/IP address, count number according to your environment)



NOTE

There is no need to add 'IPv4 Modifier' for 'Source' IP.

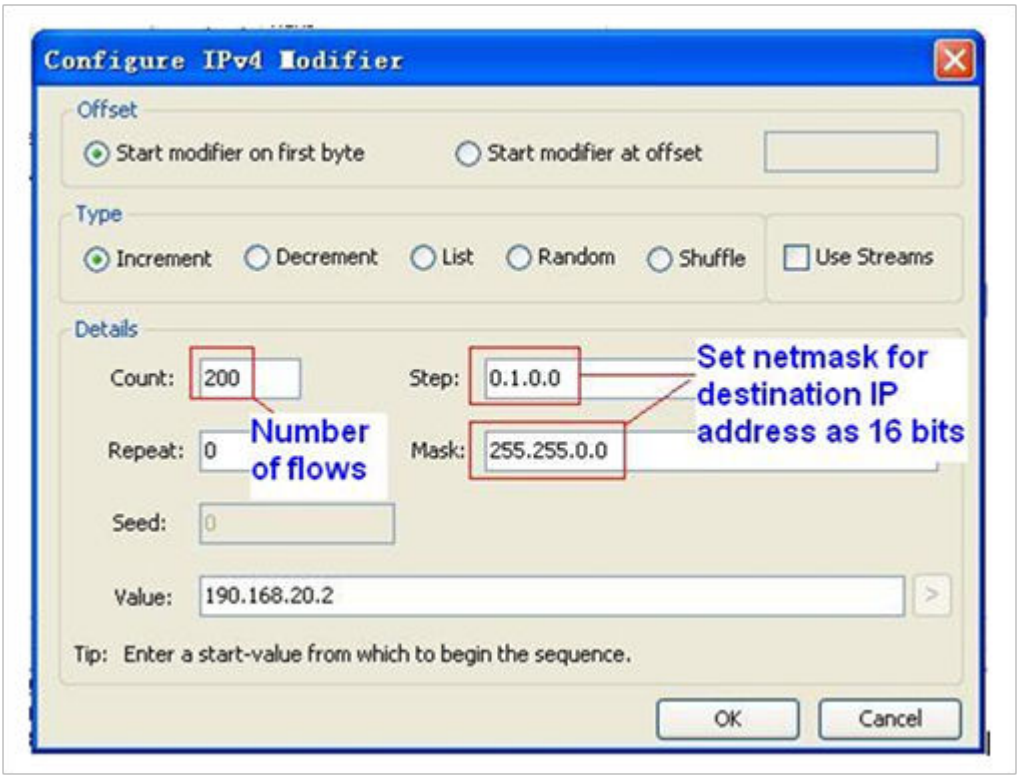


Table 641. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	204	192.168.10.2	191.0.20.2 – 191.203.20.2
Port 2 to Port 1	204	192.168.20.2	190.0.10.2 – 190.203.10.2
Port 3 to Port 4	204	192.168.40.2	194.0.50.2 – 194.203.50.2
Port 4 to Port 3	204	192.168.50.2	193.0.40.2 – 193.203.40.2
Port 5 to Port 5	204	192.168.60.2	195.0.60.2 – 195.203.60.2
Total # Flows =	1020	n/a	n/a

3. Create Command Sequencer in TestCenter and select RFC2544 Throughput template. Then set options as shown in table below.

Table 642. Command Sequencer configuration

Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Packet Loss Rate	0.001%
Packet Size	64, 128, 256, 512, 1024, 1280, 1518 bytes

4. Start TestCenter Command Sequencer to measure performance.

12.3.2.12 LPM-ipfwd for P4080DS/P5040DS/B4860QDS

Procedure for LPM-ipfwd application

1. Boot board with USDPAA mode, then execute the following commands on the board:

Table 643. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c <fman_config> –p usdpaa_policy_hash_ipv4.xml –a	xml policy file can be found in file system. <fman_config> here is: for P4080DS usdpaa_config_p4_serdes_0xe.xml; P5040DS usdpaa_config_p5_serdes_0x02.xml; B4860QDS usdpaa_config_b4_serdes_0x2a_0x98.xml

Table continues on the next page...

Table 643. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#lpm_ipfwd_app 1..3 -c <fman_config> –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports.
e	Login Linux from tftp server	ssh root@192.168.1.200	---
f	Run IP forward configuration script in ssh session	#lpm_ipfwd_20G.sh $PID	PID is the process id of lpm_ipfwd. It is printed when lpm_ipfwd starts
g	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *LPM-ipfwd for P4080DS/P5040DS/B4860QDS*, except IP address assignments.

Table 644. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	512	192.168.60.2	192.0.160.2 – 193.255.160.2
Port 2 to Port 1	512	192.168.160.2	190.0.60.2 –-- 191.255.60.2
Total # Flows =	1024	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.13 LPM-ipfwd for T2080QDS

Procedure for LPM-ipfwd application

1. Create a Shell script 'lpm_ipfwd_24G.sh' with following content:

```
pid=$1
board_type=$(uname -n)
if [ "$pid" == "" ]
        then
                echo "Give PID to hook up with"
                exit 1
fi

net_pair_routes()
{
        net=0
        while [ "$net" -le $5 ]
        do
                lpm_ipfwd_config -P $pid -B -c $2 -d $1.$net.24.2 -n $3 -g \
                192.168.$4.2
                net=`expr $net + 1`
        done
}

lpm_ipfwd_config -P $pid -F -a 192.168.0.1 -i 1
lpm_ipfwd_config -P $pid -F -a 192.168.1.1 -i 2
lpm_ipfwd_config -P $pid -F -a 192.168.2.1 -i 3
lpm_ipfwd_config -P $pid -F -a 192.168.3.1 -i 4
```

```
lpm_ipfwd_config -P $pid -F -a 192.168.8.1 -i 89
lpm_ipfwd_config -P $pid -F -a 192.168.9.1 -i 90

lpm_ipfwd_config -P $pid -G -s 192.168.0.2 -m 0F:11:22:33:44:00 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.1.2 -m 0F:11:22:33:44:01 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.2.2 -m 0F:11:22:33:44:02 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.3.2 -m 0F:11:22:33:44:03 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.8.2 -m 0F:11:22:33:44:08 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.9.2 -m 0F:11:22:33:44:09 -r true

                               # 1020
net_pair_routes 100 1 16 0 170 # 170
net_pair_routes 101 1 16 1 170 # 170
net_pair_routes 102 1 16 2 170 # 170
net_pair_routes 103 1 16 3 170 # 170
net_pair_routes 108 1 16 8 170 # 170
net_pair_routes 109 1 16 9 170 # 170
echo LPM-IPFwd Route Creation completed
```

2. Boot board with USDPAA mode, then execute the following commands on the board:

Table 645. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c <fman_config> –p usdpaa_policy_hash_ipv4.xml –a	xml policy file can be found in file system. <fman_config> here is: usdpaa_config_t2_serdes_66_15.xml for T2080QDS
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#lpm_ipfwd_app 1..3 -c <fman_config> –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports. On T2080QDS, user could get better performance with 8 cores if user adds parameter '-s' for lpm_ipfwd_app. e.g. lpm_ipfwd_app 0..7 -c usdpaa_config_t2_serdes_66_16_22g.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000 Note: If the performance for 8 core is less than 6 core on T2080QDS.Running lpm_ipfwd_app with "-s" option to bridge the gap between two conifguration.
e	Login Linux from tftp server	ssh root@192.168.1.200	---

Table continues on the next page...

Table 645. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
f	Run IP forward configuration script in ssh session	#lpm_ipfwd_24G.sh $PID	PID is the process id of lpm_ipfwd. It is printed when lpm_ipfwd starts
g	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready

3. Refer to Step 2 & 3 in the section, *LPM-ipfwd for T2080QDS*, except IP address assignments.

Table 646. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values
Port 1 to Port 2	170	101.0.24.2	100.0.24.2 – 100.169.24.2
Port 2 to Port 1	170	100.0.24.2	101.0.24.2 – 101.169.24.2
Port 3 to Port 4	170	103.0.24.2	102.0.24.2 – 102.169.24.2
Port 4 to Port 3	170	102.0.24.2	103.0.24.2 – 103.169.24.2
Port 10G 1 to Port 10G 2	170	109.0.24.2	108.0.24.2 – 108.169.24.2
Port 10G 2 to Port 10G 1	170	108.0.24.2	109.0.24.2 – 109.169.24.2
Total # Flows =	1020	n/a	n/a

4. Start TestCenter Command Sequencer to measure performance.

12.3.2.14 LPM-ipfwd for T4240QDS/T4240RDB

Procedure for LPM-ipfwd application

1. Boot board with usdpaa mode, then execute commands on board:

Table 647. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c <fman_config> –p usdpaa_policy_hash_ipv4.xml –a	<fman_config> for T4240QDS is usdpaa_config_t4_serdes_1_1_5_5.xml, for T4240RDB is usdpaa_config_t4_48g.xml

Table continues on the next page...

Table 647. Operations on board (continued)

Step	Action	Command on Linux Partition	Notes
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#lpm_ipfwd_app 1..3 -c <fman_config> –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports. Note: If the performance for 24 core is less than 16 core on T4240 board.Running lpm_ipfwd_app with "-s" option to bridge the gap between two conifguration.
e	Login Linux from tftp server	ssh root@192.168.1.200	---
f	Modify IP forwarding configuration script for T4240RDB	sed -i 's/-i 5/i 1/;s/-i 105/-i 101/' /usr/bin/lpm_ipfwd_42G.sh	Ignore this step if you are using T4240RDB
g	Run IP forwarding configuration script in ssh session	#lpm_ipfwd_42G.sh $PID	PID is the process id of lpm_ipfwd. It is printed when lpm_ipfwd starts
h	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *RC-ipfwd for T4240QDS/T4240RDB*, except IP address assignments.

Table 648. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values	NetMask
Port 1 to Port 2	224	192.168.50.2	192.0.24.2 – 192.223.24.2	255.255.0.0
Port 2 to Port 1	224	192.168.60.2	191.0.24.2 – 191.223.24.2	255.255.0.0
Port 3 to Port 4	64	192.168.40.2	193.0.24.2 – 193.63.24.2	255.255.0.0
Port 4 to Port 3	64	192.168.130.2	190.0.24.2 – 190.63.24.2	255.255.0.0
Port 5 to Port 6	224	192.168.140.2	195.0.24.2 – 195.223.24.2	255.255.0.0
Port 6 to Port 5	224	192.168.150.2	194.0.24.2 – 194.223.24.2	255.255.0.0
Total # Flows =	1024	n/a	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.15 LPM-ipfwd for T1023RDB/T1024RDB

Procedure for LPM-ipfwd application

1. Boot two board with usdpaa mode, then execute commands on each board:

Table 649. Operations on board

Step	Action	Command on Linux Partition	Notes
a	Config ethernet port	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	Get into PCD file folder	#cd /usr/etc	---
c	Configure PCD	`# fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	xml policy file can be found in file system <fman_config> is: T1023RDB: usdpaa_config_t1023_serdes_0x77.xml T1024RDB: usdpaa_config_t1024_serdes_0x99.xml
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	`# lpm_ipfwd_app 0..1 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	ssh root@192.168.1.200	---

f	Run IP forward configuration script in ssh session	`# cd /usr/bin`
		`# T1023RDB`
		`# sed -i 's/00:04:9f:01:02:05/00:e0:0c:00:76:02/g' lpm_ipfwd_t1023_4.5G.sh`
		`# sed -i 's/00:04:9f:11:12:24/00:e0:0c:00:4A:02/g' lpm_ipfwd_t1023_4.5G.sh`
		`# lpm_ipfwd_t1023_4.5G.sh $PID`
		`# T1024RDB`
		`# sed -i 's/00:04:9f:01:02:05/00:e0:0c:00:6F:00/g' lpm_ipfwd_t1024_12G.sh`
		`# sed -i 's/00:04:9f:11:12:24/00:e0:0c:00:71:00/g' lpm_ipfwd_t1024_12G.sh`
		`# lpm_ipfwd_t1024_12G.sh $PID`
			PID is the process id of lpm_ipfwd. It is printed when lpm_ipfwd starts

g	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready

2. Refer to Step 2 & 3 in the section, *LPM-ipfwd for T1023RDB/T1024RDB*, except IP address assignments.

Table 650. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values	NetMask
Board 1 Port 1 to Board 2 Port 1	256	192.168.20.2	195.0.24.2 – 195.255.24.2	255.255.0.0
Board 1 Port 2 to Board 2 Port 2	256	192.168.30.2	196.0.24.2 – 196.255.24.2	255.255.0.0
Board 2 Port 1 to Board 1 Port 1	256	192.168.20.2	193.0.24.2 – 193.255.24.2	255.255.0.0
Board 2 Port 2 to Board 1 Port 2	256	192.168.30.2	194.0.24.2 – 194.255.24.2	255.255.0.0
Total # Flows =	1024	n/a	n/a	n/a

3. Start TestCenter Command Sequencer to measure performance.

12.3.2.16 LPM-ipfwd for T1040D4RDB

Procedure for LPM-ipfwd application

1. Configure FDB entries for L2 switch through application 'l2sw_bin'

```
# l2sw_bin
l2sw_bin> mac add static 00:11:22:33:44:01 0
l2sw_bin> mac add static 00:11:22:33:44:02 1
l2sw_bin> mac add static 00:11:22:33:44:03 2
l2sw_bin> mac add static 00:11:22:33:55:03 2
l2sw_bin> mac add static 00:11:22:33:55:01 3
l2sw_bin> mac add static 00:11:22:33:55:02 4
l2sw_bin> mac add static <fm1-gb0 mac> 8   # replace <...> with real MAC address
l2sw_bin> mac add static <fm1-gb1 mac> 9   # replace <...> with real MAC address
l2sw_bin> Press Ctrl+C to quit l2sw_bin application
```

2. Create a Shell script 'lpm_ipfwd_8g_t1040d4rdb.sh' with following content:

```
pid=$1

net_pair_routes()
{
    if [ "x$6" == "x" ]
    then
        net=0
        gwip=2
    else
        net=$6
        gwip=$6
    fi

    while [ "$net" -le $5 ]
    do
        lpm_ipfwd_config -P $pid -B -c $2 -d $1.$net.24.2 -n $3 -g \
        192.168.$4.$gwip
        net=`expr $net + 1`
```

```
    done
}

lpm_ipfwd_config -P $pid -F -a 192.168.10.1 -i 0
lpm_ipfwd_config -P $pid -F -a 192.168.20.1 -i 1
lpm_ipfwd_config -P $pid -F -a 192.168.30.1 -i 2
lpm_ipfwd_config -P $pid -F -a 192.168.40.1 -i 3
lpm_ipfwd_config -P $pid -F -a 192.168.50.1 -i 4

lpm_ipfwd_config -P $pid -G -s 192.168.10.2 -m 00:11:22:33:44:01 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.10.82 -m 00:11:22:33:44:02 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.10.164 -m 00:11:22:33:44:03 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.20.2 -m 00:11:22:33:55:01 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.20.82 -m 00:11:22:33:55:02 -r true
lpm_ipfwd_config -P $pid -G -s 192.168.20.164 -m 00:11:22:33:55:03 -r true

echo LPM-IPFwd Route Creation completed
```

3. Boot board with usdpaa mode, then execute commands on board:

Table 651. Operations on board

Step	Action	Command on Linux Partition	Notes
a	---	#ifconfig eth0 192.168.1.200	set ethernet port IP addr.
b	---	#cd /usr/etc	---
c	Configure PCD	#fmc –c usdpaa_config_t1_serdes_0x66.xml –p usdpaa_policy_hash_ipv4.xml –a	
d	Launch IP forward application which creates one thread on core 1, 2 and 3 individually	#lpm_ipfwd_app 1..3 -c usdpaa_config_t1_serdes_0x66.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000	You may use any combination of available cores the platform supports
e	Login Linux from tftp server	ssh root@192.168.1.200	---
f	Run IP forward configuration script in ssh session	#lpm_ipfwd_8g_t1040d4rdb.sh $PID	PID is the process id of lpm_ipfwd. It is printed when lpm_ipfwd starts
g	Launch TestCenter project to pump traffic	---	Now the lpm_ipfwd_app is ready

4. Refer to Step 2 & 3 in the section, *LPM-ipfwd for T1040D4RDB*, except IP address assignments.

Table 652. IP addresses assignment

Packet Flow	Number of Flows	Source Values	Destination Values	NetMask
Port 1 to Port 2	204	192.168.30.2	193.0.24.2 – 193.203.24.2	255.255.0.0
Port 2 to Port 3	204	192.168.40.2	194.0.24.2 – 194.203.24.2	255.255.0.0
Port 3 to Port 1	204	192.168.50.2	192.0.24.2 – 192.203.24.2	255.255.0.0
Port 4 to Port 7	82	192.168.10.2	191.0.24.2 – 191.81.24.2	255.255.0.0
Port 5 to Port 8	82	192.168.10.2	191.82.24.2 – 191.163.24.2	255.255.0.0

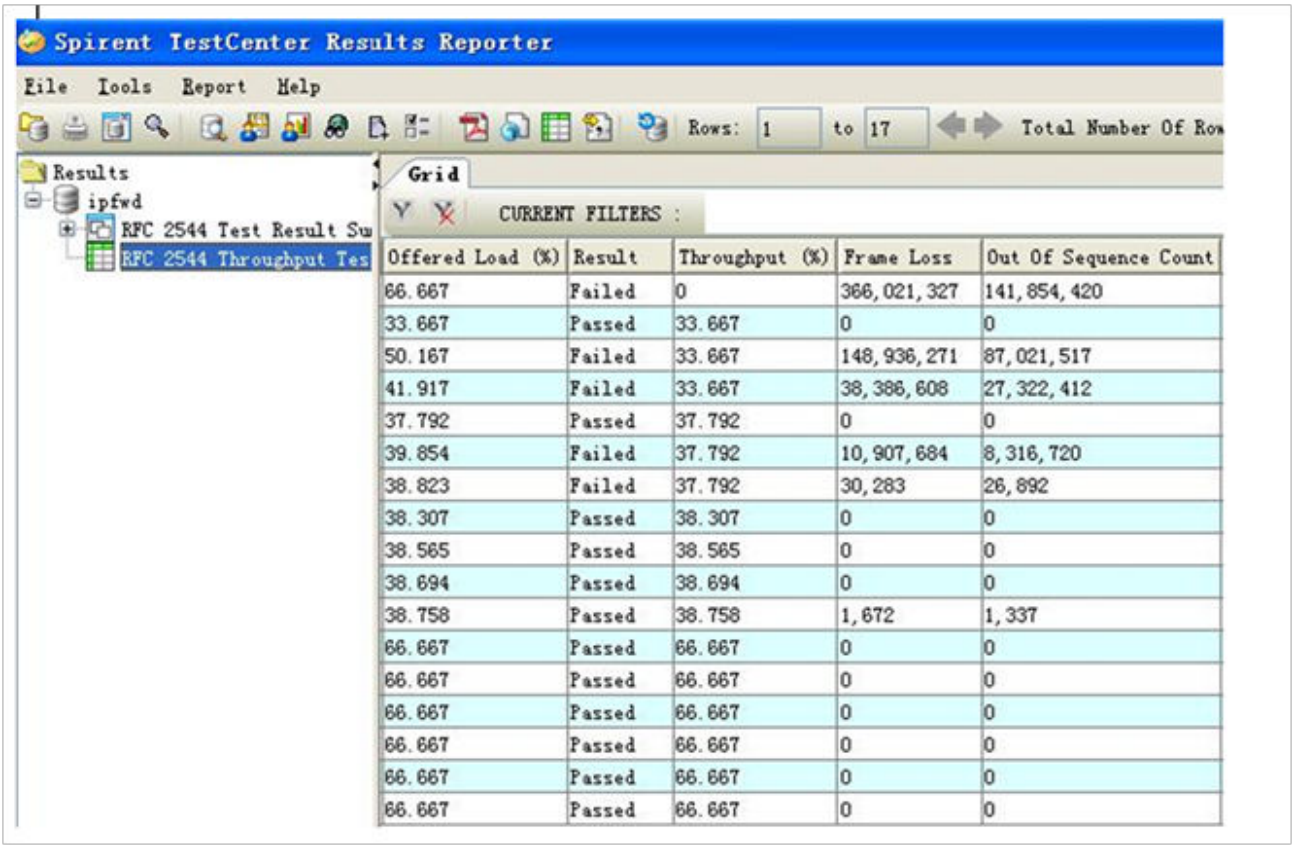
Port 4 to Port 7	82	192.168.20.2	190.0.24.2 – 190.81.24.2	255.255.0.0
Port 5 to Port 8	82	192.168.20.2	190.82.24.2 – 190.163.24.2	255.255.0.0
Total # Flows =	1024	n/a	n/a	n/a

5. Start TestCenter Command Sequencer to measure performance.

12.3.2.17 View of Test Result

To measure performance by TestCenter RFC 2544 Command Sequence, see the summary result using Spirent TestCenter Results Reporter.

If Order Preservation or Order Restoration is enabled, and TestCenter sends Zero Loss traffic, then count of Out of Sequence should be 0.



Offered Load (%)	Result	Throughput (%)	Frame Loss	Out Of Sequence Count
66.667	Failed	0	366,021,327	141,854,420
33.667	Passed	33.667	0	0

12.3.3.3 Application and Traffic Flow

USDPAA IPSec forwarding supports two types of packet processes: encryption and decryption. Each process can work independently. The user must specify the process type for each flow. It Contains two applications:

- ipsecfwd_app: The application that takes charge of initializing devices, managing threads and buffers and packet processing
- ipsecfwd_config: The command line interface(CLI) that configures ipsecfwd, such as IP address assignments to each port and IP and ARP route management.

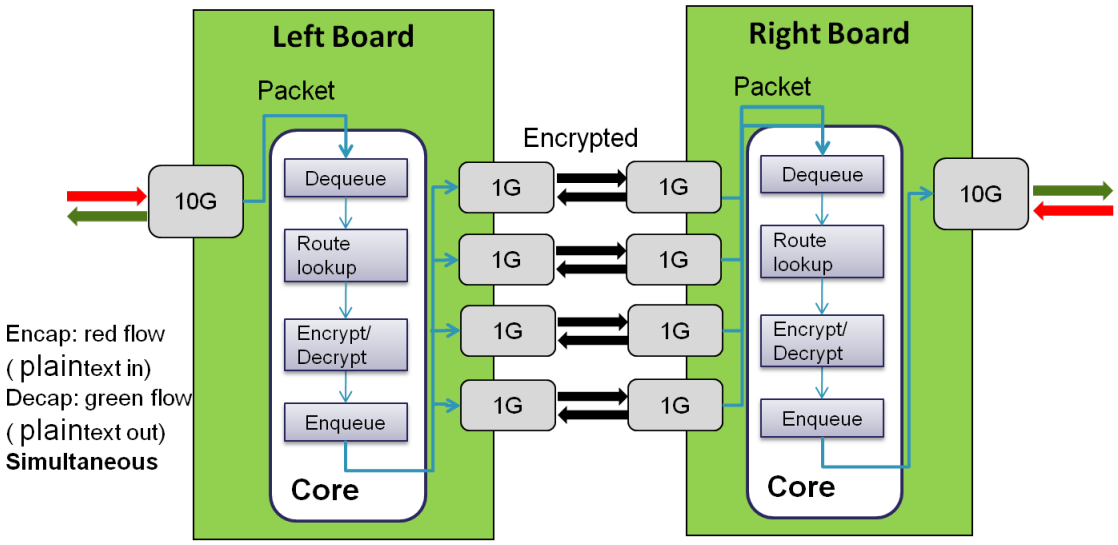
IPSec Forwarding Traffic Flow

Since Spirent TestCenter Command Sequencer (throughput measurement tool) doesn't support encrypted packets, the user must ensure that both the ingress packets to target and the egress packets from target are plain text.

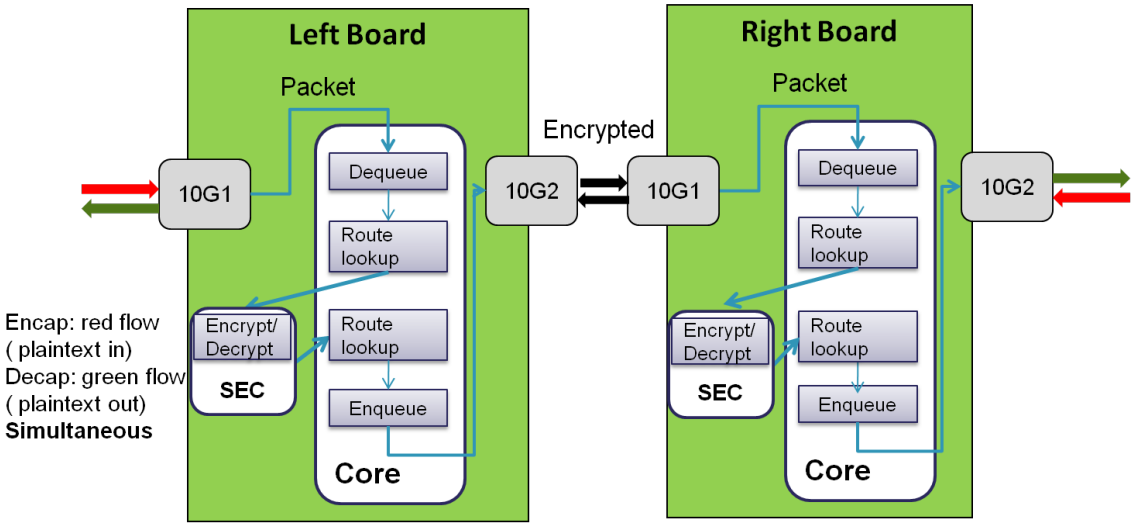
In this case, we design a traffic flow called IPSec forwarding back-to-back, wherein packets go through encryption on left target and decryption on right target in sequence, thus plaintext packets are eventually received by TestCenter.

IPSec forwarding traffic flow varies for different platforms:

On P2041RBD/P3041DS/P5020DS, 14G IPSec forwarding (aggregated throughput is 8 Gbps) is supported.



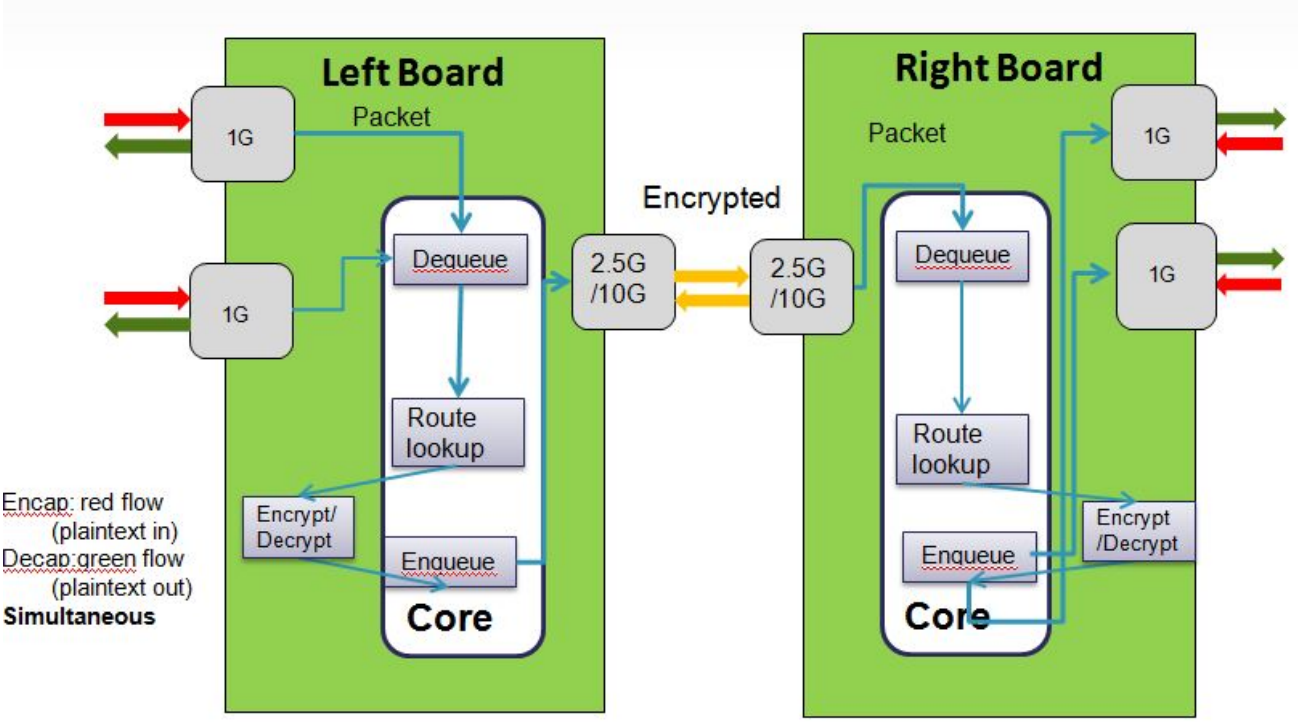
On P4080DS/P5040DS/B4860QDS/LS1046ARDB, 20G IPSec forwarding is supported; On T4240QDS/T4240RDB, 40G IPSec forwarding is supported.



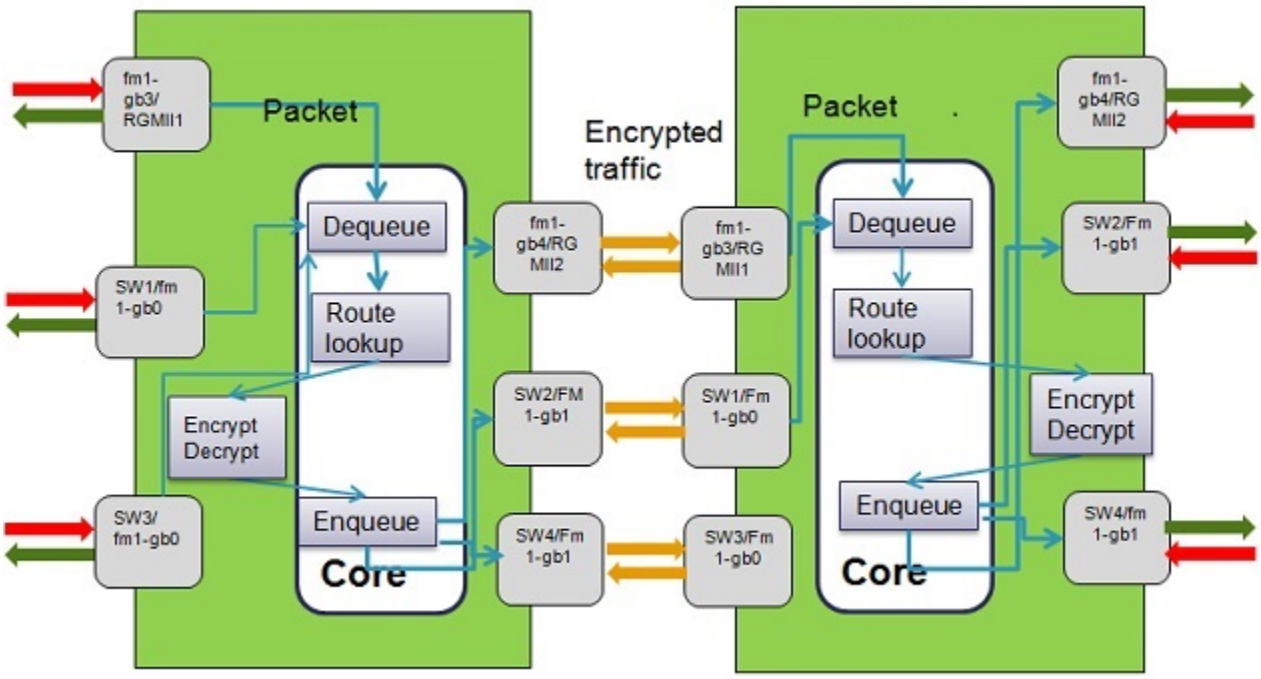
NOTE

Compared to the 20G setup, the 40G setup has two additional 10G ports on each board.

On T1023RDB/T1024RDB, 4G IPSec forwarding is supported



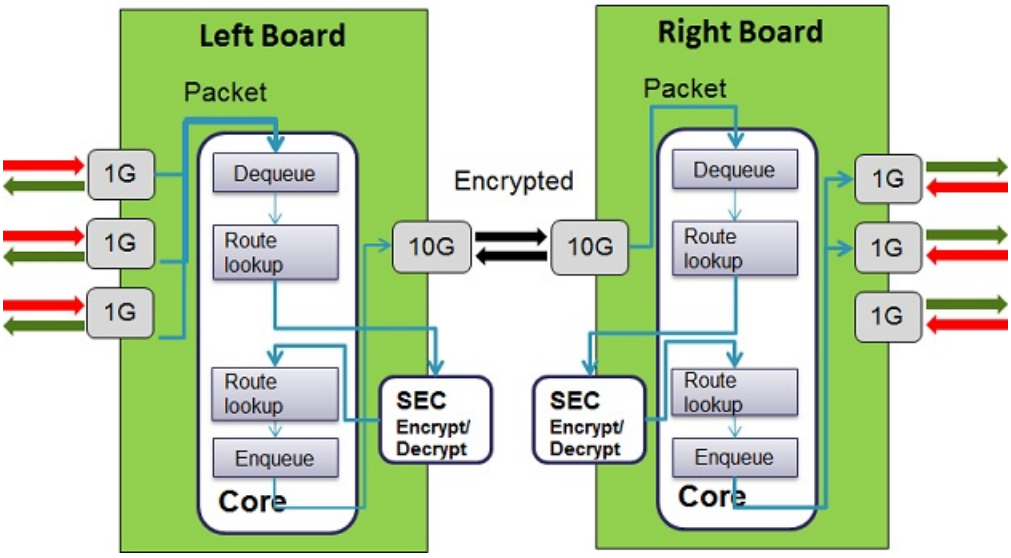
On T1040D4RDB, 6G IPSec forwarding is supported



NOTE

SW*n* is network interface on L2 switch, *n* is its index.

On LS1043ARDB, 13G IPsec forwarding is supported



DPAA Resource Configuration

Table 655. DPAA Resource Configuration for USDPAA IPSec Forwarding

DPAA Resource	USDPAA IPSec Forwarding Function

FMan	• Parsing on 32 bytes: parser result comes with every frame.
	  • Protocol parsing
	  • IP Header location
	  • IP Header checksum check
	  • Error code
	• Congestion management disabled. Fman side order restoration is on.
	• Hash is based on the SIP, DIP for encrypt; SIP, DIP, SPI for decrypt

QMan	• Push mode, Triple dequeue enable.
	• DQRR:
	  • Entry Stashing on.
	  • To L1 cache, with high priority.
	• Frame data, Annotation, Context stashing on: –Frame data = 1 line, Annotation = 1 line, Context = 1
	• Consumer Index write mode cache-inhibited: Update on every 3 frames dequeue.
	• EQRR: Access through Cache Enable Access (CENA, WIMGE=00000)

BMan	• Buffer Pool: bp9 • Buffer Size: 1728 Bytes • Number of buffers: 8192
DMA Memory	• 256MB for 32 bit platform • 256MB for 64 bit platform

12.3.3.4 IPSec Forwarding for P2041RDB/P3041DS/P5020DS

Procedure for ipsecfwd application

Assumption regarding MAC address

We assume the following regarding MAC addresses in the IPSecfwd configuration script (ipsecfwd_mix_15G.sh):

- 4 1G ports on left board: 00:e0:0c:00:e5:00/01/03/04
- 4 1G ports on right board: 00:e0:0c:00:cb:00/01/03/04

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with this assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

If using 10G, the user needs to set the hwconfig U-Boot variable before booting into Linux. Once hwconfig is set, boot board with usdpaa mode, then execute the following commands on board:

Table 656. Operations on board

Step Number	Action	Command on Linux Partition	Notes
1	---	`#ifconfig eth0 192.168.1.200`	Commands on Linux of **LEFT** board Ports other than eth0 can also be used
2	---	`#cd /usr/etc`	---
3	Configure PCD	`#fmc –c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –a`	---
4	Launch IPSec forward application which creates one thread on core 1, 2 and 3 individually	`#ipsecfwd_app <cpu_range> -c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000`	You may use any combination of available cores the platform supports.
5	Login Linux from tftp server	`ssh root@192.168.1.200`	---
6	Run IP forward configuration script in ssh session	`# sed -i '/168.30/d' /usr/bin/ipsecfwd_mix_15G.sh` `#ipsecfwd_mix_15G.sh left $PID`	PID is the process id of ipsecfwd application. It is printed when the application starts
7	---	`# ifconfig eth0 192.168.1.100`	Commands on Linux of **RIGHT** board Ports other than eth0 can also be used
8	---	`# cd /usr/etc`	---
9	Configure PCD	`#fmc –c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –a`	---
10	Launch IP forward application	`#ipsecfwd_app 1..3 -c usdpaa_config_p2_p3_p5_14g.xml –p usdpaa_policy_hash_ipv4.xml –d 0x10000000`	---
11	Login Linux from tftp server	`ssh root@192.168.1.100`	---

Table continues on the next page...

Table 656. Operations on board (continued)

Step Number	Action	Command on Linux Partition	Notes
12	Run IP forward configuration script in ssh session	`# sed -i '/168.30/d' /usr/bin/ipsecfwd_mix_15G.sh` `#ipsecfwd_mix_15G.sh right $PID`	---
13	Launch TestCenter project to pump traffic	---	Now the ipsecfwd_app is ready to receive traffic

Step 2:

Create ‘Raw Stream’ in generator for each port, and compose packet as following:

- Change Mac/IP address
- Set "Count" to the appropriate number of source and destination addresses

Table 657. IP addresses assignment - Left to Right (500 flows)

Stream #	Source Values	Destination Values
1	192.168.60.2 – 192.168.60.11	192.168.10.2 – 192.168.10.11
2	192.168.60.2 – 192.168.60.11	192.168.20.2 – 192.168.20.11
3	192.168.60.2 – 192.168.60.11	192.168.40.2 – 192.168.40.11
4	192.168.60.2 – 192.168.60.11	192.168.50.2 – 192.168.50.11

Table 658. IP addresses assignment - Right to Left (500 flows)

Stream #	Source Values	Destination Values
1	192.168.10.2 – 192.168.10.11	192.168.60.2 – 192.168.60.11
2	192.168.20.2 – 192.168.20.11	192.168.60.2 – 192.168.60.11
3	192.168.40.2 – 192.168.40.11	192.168.60.2 – 192.168.60.11
4	192.168.50.2 – 192.168.50.11	192.168.60.2 – 192.168.60.11

Total = 1000 flows

Step 4:

Start TestCenter Command Sequencer to measure performance.

12.3.3.5 IPSec Forwarding for P4080DS/P5040DS/B4860QDS/ LS1046ARDB

Procedure for ipsecfwd application

Assumption regarding MAC address

We assume the following regarding MAC addresses in IPSecfwd configuration script (ipsecfwd_mix_20G.sh):

- Port 10G2 on left board: 00:e0:0c:00:8a:09
- Port 10G1 on right board: 00:e0:0c:00:e2:04

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with the assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

If using 10G, the user needs to set the hwconfig U-Boot variable before booting into Linux. Once hwconfig is set, boot board with usdpaa mode, then execute the following commands on board:

Table 660. Operations on board

Step Number	Action	Command on Linux Partition	Notes
1	---	`#ifconfig eth0 192.168.1.200`	Commands on Linux of **LEFT** board Ports other than eth0 can also be used
2	---	`#cd /usr/etc`	---
3	Configure PCD	`#fmc –c <fmc_config> –p usdpaa_policy_hash_ipv4.xml –a`	XML policy file can be found in file system. <fman_config> is: for P4080DS usdpaa_config_p4_serdes_0xe.xml ; P5040DS usdpaa_config_p5_serdes_0x02.xml; B4860QDS usdpaa_config_b4_serdes_0x2a_0x98.xml; LS1046ARDB usdpaa_config_ls1046.xml
4	Launch IPSec forward application which creates one thread on core 1, 2 and 3 individually	`#ipsecfwd_app 1..3 -c <fmc_config> –p usdpaa_policy_hash_ipv4.xml –d 0x10000000`	You may use any combination of available cores the platform supports.
5	Login Linux from tftp server	ssh root@192.168.1.200	---
6	Run IP forward configuration script in ssh session	`#ipsecfwd_mix_20G.sh left $PID`	PID is the process id of ipsecfwd application. It is printed when the application starts
7	---	`# ifconfig eth0 192.168.1.100`	commands on Linux of **RIGHT** board Ports other than eth0 can also be used

Table continues on the next page...

Table 660. Operations on board (continued)

Step Number	Action	Command on Linux Partition	Notes
8	---	`# cd /usr/etc`	---
9	Configure PCD	`#fmc -c <fmc_config> -p usdpaa_policy_hash_ipv4.xml -a`	See 4
10	Launch IP forward application	`#ipsecfwd_app 1..3 -c <fmc_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	---
11	Login Linux from tftp server	`ssh root@192.168.1.100`	---
12	Run IP forward configuration script in ssh session	`#ipsecfwd_mix_20G.sh right $PID`	---
13	Launch TestCenter project to pump traffic	---	Now the ipsecfwd_app is ready to receive traffic

Step 2:

Create ‘Raw Stream’ in generator for each port, and compose packet as following:

- Change Mac/IP address
- Set "Count" to the appropriate number of source and destination addresses

Table 661. IP addresses assignment - Left to Right (506 flows)

Stream #	Source Values	Destination Values
1	192.168.60.2 – 192.168.60.23	192.168.160.2 – 192.168.160.24

Table 662. IP addresses assignment - Right to Left (506 flows)

Stream #	Source Values	Destination Values
1	192.168.160.2 – 192.168.160.23	192.168.60.2 – 192.168.60.24

Total = 1012 flows

Step 3:

Create Command Sequencer in TestCenter and select RFC2544 Throughput test. Then set Test Parameters for TestCenter Throughput Sequencer as shown in table below.

Table 663. Spirent TestCenter Throughput Configuration

Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Packet Loss Rate	0.001%
Packet Size	82, 408, 1442 bytes

Step 4:

Start TestCenter Command Sequencer to measure performance.

12.3.3.6 IPSec Forwarding for T4240QDS

Procedure for ipsecfwd application

Assumption regrading MAC address

We assume the following regarding MAC addresses in IPSecfwd configuration script (ipsecfwd_mix_40G.sh):

- Port 10G2 & 10G4 on left board: 00:e0:0c:00:8a:09/0a
- Port 10G1 & 10G3 on right board: 00:e0:0c:00:e2:04/05

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with the assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

If using 10G, the user needs to set the hwconfig U-Boot variable before booting into Linux. Once hwconfig is set, boot board with usdpaa mode, then execute the following commands on board:

Table 664. Operations on board

Step Number	Action	Command on Linux Partition	Notes
1	---	`#ifconfig eth0 192.168.1.200`	Commands on Linux of **LEFT** board Ports other than eth0 can also be used
2	---	`#cd /usr/etc`	---
3	Configure PCD	`#fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	<fman_config> for T4240QDS is usdpaa_config_t4_serdes_1_1_5_5.xml, for T4240RDB is usdpaa_config_t4_48g.xml
4	Launch IPSec forward application which creates one thread on core 1, 2 and 3 individually	`#ipsecfwd_app 1..3 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	You may use any combination of available cores the platform supports.
5	Login Linux from tftp server	`ssh root@192.168.1.200`	---
6	Run IP forward configuration script in ssh session	`#ipsecfwd_mix_40G.sh left $PID`	PID is the process id of ipsecfwd application. It is printed when the application starts
7	---	`# ifconfig eth0 192.168.1.100`	Commands on Linux of **RIGHT** board Ports other than eth0 can also be used
8	---	`# cd /usr/etc`	---

Table continues on the next page...

Table 664. Operations on board (continued)

Step Number	Action	Command on Linux Partition	Notes
9	Configure PCD	`#fmc -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -a`	See 3
10	Launch IP forward application	`#ipsecfwd_app 1..3 -c <fman_config> -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	---
11	Login Linux from tftp server	`ssh root@192.168.1.100`	---
12	Run IP forward configuration script in ssh session	`#ipsecfwd_mix_40G.sh right $PID`	---
13	Launch TestCenter project to pump traffic	---	Now the ipsecfwd_app is ready to receive traffic

Step 2:

Create ‘Raw Stream’ in generator for each port, and compose packet as following:

- Change Mac/IP address
- Set "Count" to the appropriate number of source and destination addresses

Table 665. IP addresses assignment - Left to Right (512 flows)

Stream #	Source Values	Destination Values
1	192.168.60.2 – 192.168.60.17	192.168.160.2 – 192.168.160.17
2	192.168.70.2 – 192.168.70.17	192.168.170.2 – 192.168.170.17

Table 666. IP addresses assignment - Right to Left (512 flows)

Stream #	Source Values	Destination Values
1	192.168.160.2 – 192.168.160.17	192.168.60.2 – 192.168.60.17
2	192.168.170.2 – 192.168.170.17	192.168.70.2 – 192.168.70.17

Total = 1024 flows

Step 4:

Start TestCenter Command Sequencer to measure performance.

12.3.3.7 IPSec Forwarding for T1023RDB/T1024RDB

Procedure for ipsecfwd application

Assumption regrading MAC address

We assume the following regarding MAC addresses in IPSecfwd configuration script (ipsecfwd_t1023_mix_4.5G.sh, ipsecfwd_t1024_mix_12G.sh):

- Port fm1-mac3 and fm1-mac4 on left board: 00:e0:0c:00:71:02/03
- Port fm1-mac3 and fm1-mac4 on right board: 00:e0:0c:00:6f:02/03

Note: For T1023RDB, used fm1-mac1 instead of fm1-mac3, port id is 0

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with the assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

If using 10G, the user needs to set the hwconfig U-Boot variable before booting into Linux. Once hwconfig is set, boot board with usdpaa mode, then execute the following commands on board:

Table 668. Operations on board

Step Number	Action	Command on Linux Partition	Notes
1	---	`#ifconfig eth0 192.168.1.200`	Commands on Linux of **LEFT** board Ports other than eth0 can also be used
2	---	`#cd /usr/etc`	---
3	Configure PCD	`#fmc -c usdpaa_config_t1024_serdes_0x99.xml -p usdpaa_policy_hash_ipv4.xml -a`	---
4	Launch IPSec forward application which creates one thread on core 0 and 1 individually	`#ipsecfwd_app 0..1 -c usdpaa_config_t1024_serdes_0x99.xml -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	Input 0 or 1 instead of 0..1 to launch single data processing thread on core 0 or core 1
5	Login Linux from tftp server	`ssh root@192.168.1.200`	---

Table continues on the next page...

Table 668. Operations on board (continued)

Step Number	Action	Command on Linux Partition	Notes

6	Modify IPSec forwarding configuration script	`sed -i 's/e2:1e/6F:02/g;t;s/8a:1e/71:02/g' <ipsecfwd_config_script>`
		`sed -i 's/e2:28/6F:03/g;t;s/8a:28/71:03/g' <ipsecfwd_config_script>`
		`sed -i 's/00:04:9f:01:02:05/00:e0:0c:00:6F:00/g;t;s/00:04:9f:11:12:24/00:e0:0c:00:71:00/g' <ipsecfwd_config_script>`
			<ipsecfwd_config_script> for T1023RDB is ipsecfwd_t1023_mix_4.5G.sh, for T1024RDB is ipsecfwd_t1024_mix_12G.sh.

7	Run IP forward configuration script in ssh session	`#ipsecfwd_t1024_mix_12G.sh left $PID`	PID is the process id of ipsecfwd application. It is printed when the application starts
8	---	`# ifconfig eth0 192.168.1.100`	Commands on Linux of **RIGHT** board Ports other than eth0 can also be used
9	---	`# cd /usr/etc`	---

Step 4:

Start TestCenter Command Sequencer to measure performance.

12.3.3.8 IPSec Forwarding for T1040D4RDB

Procedure for ipsecfwd application

Assumption regrading MAC address

We assume the following regarding MAC addresses in IPSecfwd configuration script (ipsecfwd_mix_40G.sh):

- Port 1G1, 1G2, 1G4 & 1G5 on left board: 00:e0:0c:00:8a:00/01/03/04
- Port 1G1, 1G2, 1G4 & 1G5 on right board: 00:e0:0c:00:e2:00/01/03/04

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with the assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

Configure FDB entries for L2 switch through application 'l2sw_bin'

```
Left board:
# l2sw_bin
l2sw_bin> mac add 00:11:22:33:44:01 0
l2sw_bin> mac add 00:11:22:33:55:01 1
l2sw_bin> mac add 00:11:22:33:44:02 2
l2sw_bin> mac add 00:11:22:33:55:02 3
l2sw_bin> mac add 00:e0:0c:00:8a:00 8
l2sw_bin> mac add 00:e0:0c:00:e2:01 9
l2sw_bin> mac add 00:11:22:33:22:01 9
l2sw_bin> mac add 00:11:22:33:22:02 9
l2sw_bin> Press Ctrl+C to quit l2sw_bin application

Right board:
l2sw_bin> mac add 00:e0:0c:00:e2:00 8
l2sw_bin> mac add 00:e0:0c:00:e2:01 9
l2sw_bin> mac add 00:11:22:33:55:01 8
l2sw_bin> mac add 00:11:22:33:55:02 8
l2sw_bin> mac add 00:11:22:33:22:01 0
l2sw_bin> mac add 00:11:22:33:33:01 1
l2sw_bin> mac add 00:11:22:33:22:02 2
l2sw_bin> mac add 00:11:22:33:33:02 3
l2sw_bin> Press Ctrl+C to quit l2sw_bin application
```

Step 2:

Create a Shell script 'ipsecfwd_mix_6G.sh' on both boards with following content

```
pid=$2
if [ "$pid" == "" ]
    then
        echo "Give PID to hook up with"
        exit 1
fi

ipsecfwd_config -P $pid -F -a 192.168.60.1 -i 0
ipsecfwd_config -P $pid -F -a 192.168.70.1 -i 3
ipsecfwd_config -P $pid -F -a 192.168.160.1 -i 1
ipsecfwd_config -P $pid -F -a 192.168.170.1 -i 4

if [ "$1" == "left" ]
then
    i=2
    while [ "$i" -le 14 ]
    do
#set the mac address of the right board here for creating ARP entry
```

```
      ipsecfwd_config -P $pid -G -s 192.168.70.$i -m 00:e0:0c:00:2a:05 -r true
      ipsecfwd_config -P $pid -G -s 192.168.170.$i -m 00:e0:0c:00:e2:03 -r true
      i=`expr $i + 1`
    done

    i=2
    while [ "$i" -le 19 ]
    do
        if [ "$i" -le 10 ]
        then
            ipsecfwd_config -P $pid -G -s 192.168.60.$i -m 00:11:22:33:44:01 -r true
            ipsecfwd_config -P $pid -G -s 192.168.160.$i -m 00:11:22:33:55:01 -r true
        else
            ipsecfwd_config -P $pid -G -s 192.168.60.$i -m 00:11:22:33:44:02 -r true
            ipsecfwd_config -P $pid -G -s 192.168.160.$i -m 00:11:22:33:55:02 -r true
        fi
        i=`expr $i + 1`
    done

    f=out
    s=in
fi

if [ "$1" == "right" ]
then
    i=2
    while [ "$i" -le 14 ]
    do
#set the mac address of the left board here for creating ARP entry
      ipsecfwd_config -P $pid -G -s 192.168.70.$i -m 00:e0:0c:00:8a:04 -r true
      ipsecfwd_config -P $pid -G -s 192.168.170.$i -m 00:e0:0c:00:4b:05 -r true
      i=`expr $i + 1`
    done

    i=2
    while [ "$i" -le 19 ]
    do
        if [ "$i" -le 10 ]
        then

9	---	`# cd /usr/etc`	---
10	Configure PCD	`#fmc -c usdpaa_config_t1_serdes_0x66.xml -p usdpaa_policy_hash_ipv4.xml -a`	See 4
11	Launch IP forward application	`#ipsecfwd_app 1..3 -c usdpaa_config_t1_serdes_0x66.xml -p usdpaa_policy_hash_ipv4.xml -d 0x10000000`	---
12	Set fm1-gb0 to promiscuous mode under prompt of ipsecfwd_app	> promisc enable f:0 p:0	---
13	Login Linux from tftp server	`ssh root@192.168.1.100`	---
14	Run IP forward configuration script in ssh session	`#ipsecfwd_mix_6G_t1040.sh right $PID`	---
15	Launch TestCenter project to pump traffic	---	Now the ipsecfwd_app is ready to receive traffic

Step 4:

Create ‘Raw Stream’ in generator for each port, and compose packet as following:

- Change Mac/IP address
- Set "Count" to the appropriate number of source and destination addresses

Table 673. IP addresses assignment - Left to Right (511 flows)

Stream #	Ingress -> Egress Ports	Source Values	Destination Values
1	fm1-gb3(L) -> fm1-gb4(R)	192.168.70.2 – 192.168.70.14	192.168.170.2 – 192.168.170.14
2	SW1(L) -> SW2(R)	192.168.60.2 – 192.168.60.20	192.168.160.2 – 192.168.160.10
3	SW3(L) -> SW4(R)	192.168.60.2 – 192.168.60.20	192.168.160.11 – 192.168.160.19

Table 674. IP addresses assignment - Right to Left (511 flows)

Stream #	Ingress -> Egress Port	Source Values	Destination Values
1	fm1-gb4(R) -> fm1-gb3(L)	192.168.170.2 – 192.168.170.14	192.168.70.2 – 192.168.70.14
2	SW2(R) -> SW1(L)	192.168.160.2 – 192.168.160.20	192.168.60.2 – 192.168.60.10
3	SW4(R) -> SW3(L)	192.168.160.2 – 192.168.160.20	192.168.60.11– 192.168.60.19

Total = 1022 flows

Step 5:

Create Command Sequencer in TestCenter and select RFC2544 Throughput test. Then set Test Parameters for TestCenter Throughput Sequencer as shown in table below.

Table 675. Spirent TestCenter Throughput Configuration

Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Packet Loss Rate	0.001%
Packet Size	82, 408, 1442 bytes

Step 6:

Start TestCenter Command Sequencer to measure performance.

12.3.3.9 IPSec Forwarding for LS1043

Procedure for ipsecfwd application

Assumption regarding MAC address

We assume the following regarding MAC addresses in IPSecfwd configuration script (ipsecfwd_ls1043a_mix_13G.sh):

- Port 10G on left board: 00:04:9f:01:02:05
- Port 10G on right board: 00:04:9f:11:12:24

User has to change the MAC addresses in the script if the real MAC addresses are not compliant with the assumption.

If user enables promiscuous mode on these ports, this assumption could be ignored.

Step 1:

If using 10G, the user needs to set the hwconfig U-Boot variable before booting into Linux. Once hwconfig is set, boot board with usdpaa mode, then execute the following commands on board:

Table 676. Operations on board

Step Number	Action	Command on Linux Partition	Notes
1	---	`#ifconfig eth0 192.168.2.65`	Commands on Linux of **LEFT** board
2	---	`#cd /usr/etc`	---
3	Configure PCD	`#fmc –c usdpaa_config_ls1043.xml –p usdpaa_policy_hash_ipv4.xml –a`	XML policy file and config can be found in file system.
4	Launch IPSec forward application which creates one thread on core 0, 1, 2 and 3 individually	`#ipsecfwd_app 0..3 -c usdpaa_config_ls1043.xml –p usdpaa_policy_hash_ipv4.xml`	You may use any combination of available cores the platform supports.
5	Login to the board using ssh	ssh root@192.168.2.65	---
6	Run IPsec forward configuration script in ssh session	`#ipsecfwd_ls1043a_mix_13G.sh left $PID`	PID is the process id of ipsecfwd application. It is printed when the application starts
7	---	`#ifconfig eth0 192.168.2.65`	commands on Linux of **RIGHT** board Ports other than eth0 can also be used
8	---	`# cd /usr/etc`	---
9	Configure PCD	`#fmc –c usdpaa_config_ls1043.xml –p usdpaa_policy_hash_ipv4.xml –a`	See 3

Table continues on the next page...

Table 676. Operations on board (continued)

Step Number	Action	Command on Linux Partition	Notes
10	Launch IPSec forward application	`#ipsecfwd_app 0..3 -c usdpaa_config_ls1043.xml -p usdpaa_policy_hash_ipv4.xml`	---
11	Login Linux from tftp server	`ssh root@192.168.2.65`	---
12	Run IPSec forward configuration script in ssh session	`#ipsecfwd_ls1043a_mix_13G.sh right $PID`	---
13	Launch TestCenter project to pump traffic	---	Now the ipsecfwd_app is ready to receive traffic

Step 2:

Create ‘Raw Stream’ in generator for each port, and compose packet as following:

- Change Mac/IP address
- Set "Count" to the appropriate number of source and destination addresses

Table 677. IP addresses assignment - Left to Right (507 flows:169*3)

Stream #	Source Values	Destination Values
1	192.168.10.2 – 192.168.10.14	192.168.20.2 - 192.168.20.14
2	192.168.30.2 – 192.168.40.14	192.168.40.2 - 192.168.30.14
3	192.168.50.2 – 192.168.60.14	192.168.60.2 - 192.168.50.14

Table 678. IP addresses assignment - Right to Left (507 flows: 169*3)

Stream #	Source Values	Destination Values
1	192.168.20.2 - 192.168.20.14	192.168.10.2 – 192.168.10.14
2	192.168.40.2 - 192.168.30.14	192.168.30.2 – 192.168.40.14
3	192.168.60.2 - 192.168.50.14	192.168.50.2 – 192.168.60.14

Total = 1014 flows

Step 3:

Create Command Sequencer in TestCenter and select RFC2544 Throughput test. Then set Test Parameters for TestCenter Throughput Sequencer as shown in table below.

Table 679. Spirent TestCenter Throughput Configuration

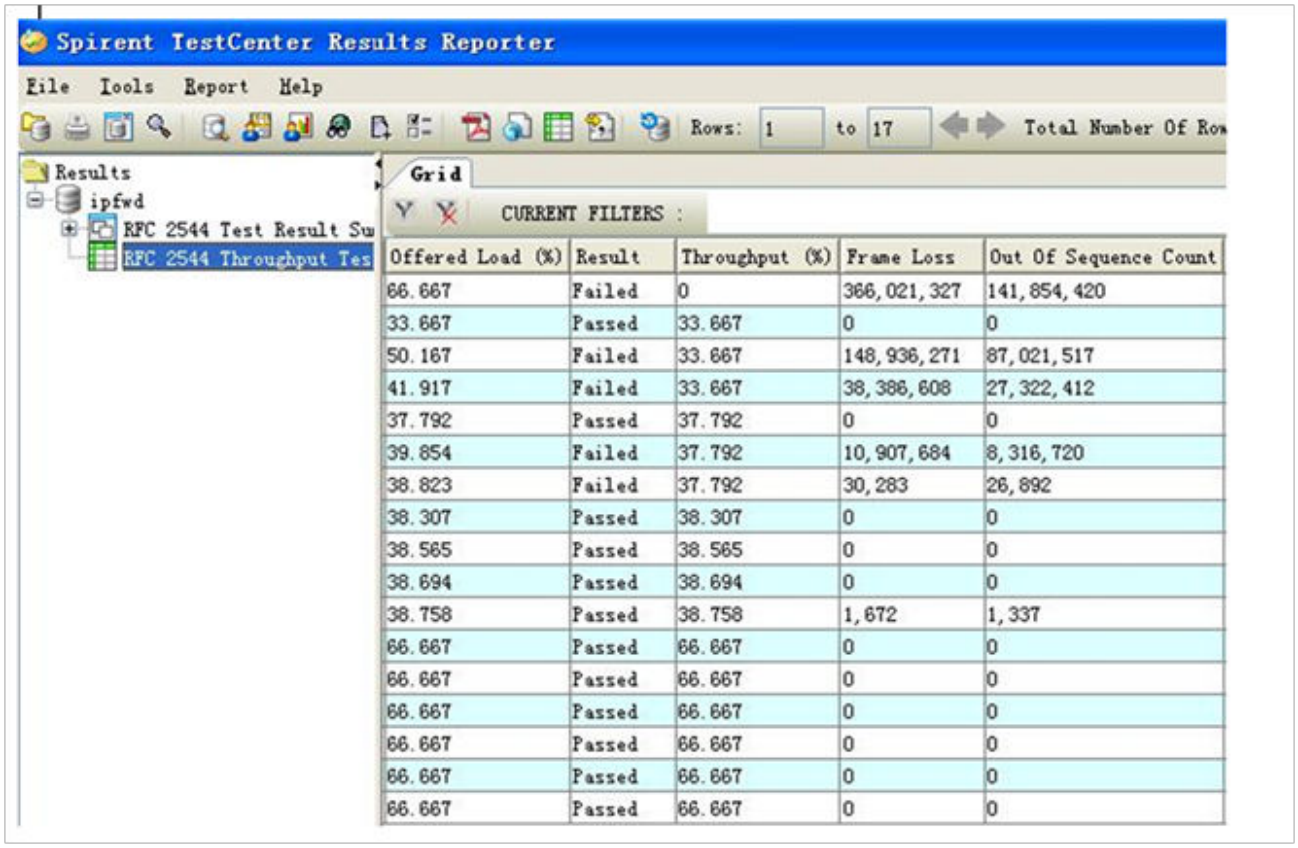
Spirent variable	Variable Setting
Test Duration	60 seconds
Resolution	0.1%
Packet Loss Rate	0.001%
Packet Size	82, 408, 1442 bytes

Step 4:

Start TestCenter Command Sequencer to measure performance.

12.3.3.10 View of Test Result

When measuring performance using TestCenter RFC 2544 Command Sequence, the result summary can be viewed using the Spirent TestCenter Results Reporter. To prevent any "out of sequence" packets when measuring with Zero Loss Throughput, enable Order Preservation or Order Restoration.



Offered Load (%)	Result	Throughput (%)	Frame Loss	Out Of Sequence Count
66.667	Failed	0	366,021,327	141,854,420
33.667	Passed	33.667	0	0
50.167	Failed	33.667	148,936,271	87,021,517
41.917	Failed	33.667	38,386,608	27,322,412
37.792	Passed	37.792	0	0
39.854	Failed	37.792	10,907,684	8,316,720
38.823	Failed	37.792	30,283	26,892
38.307	Passed	38.307	0	0
38.565	Passed	38.565	0	0
38.694	Passed	38.694	0	0

12.3.4.2 Application configuration

Software Configuration

Table 682. Software configuration

Application	Description

Linux kernel change	The SDK includes source code for Linux. 'It is necessary to enable the RapidIO UIO driver and RapidIO Message Manager driver in the kernel module configuration.
	`Device Drivers  --->`
	`<*> Userspace I/O drivers  --->`
	`<*>  Freescale Serial RapidIO support`
	`[*] Staging drivers  --->`
	`[*]  Freescale RapidIO Message Manager support`

USDPAA FRA Application Suite	FRA is a multi-thread USDPAA application that runs simultaneously on one or more boards which are connected with RapidIO cable. FRA application forwards IPv4 packets from one Ethernet interface to another boards using RapidIO transaction.

DPAA resource configuration

Table 683. DPAA resource configuration

DPAA Resource	USDPAA FRA Function
FMan	• Hash is based on the SIP,DIP

QMan	• Push mode, Triple dequeue enable.
	• DQRR:
	  • Entry Stashing on.
	  • To L1 cache, with high priority.
	• Frame data, Annotation, Context stashing on: –Frame data = 1 line, Annotation = 1 line, Context = 1
	• Consumer Index write mode cache-inhibited: Update on every 3 frames dequeue.
	• EQRR: Access through Cache Enable Access (CENA, WIMGE=00000)

BMan	• Buffer Pool: bp10
	  • Store doorbell messages
	  • Buffer Size: 80 Bytes
	  • Number of buffers: 256
	• Buffer Pool: bp11
	  • Store data-streaming/mailbox messages
	  • Buffer Size: 1600 Bytes
	  • Number of buffers: 8192
	• Buffer Pool: bp12
	  • Store s/g tables
	  • Buffer Size: 64 Bytes
	  • Number of buffers: 8192

DMA Memory	• 256MB for 32-bit platform • 256MB for 64-bit platform
RMan	• Enable error frame queue (only for T4240QDS) • Enable Outbound Segmentation Interleaving
sRIO port	• 4x LP-Serial link interfaces • Transmission rates of 5 Gbps (data rates of 4.0 Gbps) per lane • 4 x lane mode

12.3.4.3 Test Procedure

RMan performance is measure by USDPAA FRA.

FRA Working Flows

The FRA application can run on two boards at the same time. The two boards acting as host and agent are connected together with a RapidIO cable. FRA first parses the configuration, and then creates threads to do packet processing. FRA provides two packet processing flows: Processing1 and Processing2.

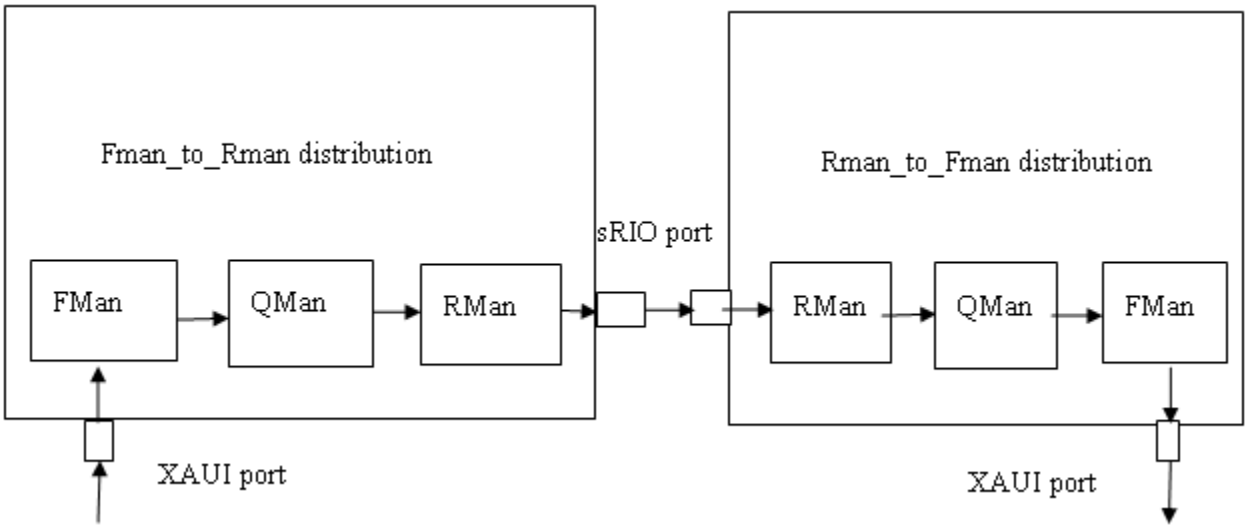

Figure 419. Packet Processing - Processing1

In the Processing1 flow, the RMan directly enqueues the packets to FMan dedicated transmission channel. Then, the FMan directly enqueues the packets to RMan dedicated transmission channel, and the core does not need to participate in the processing.

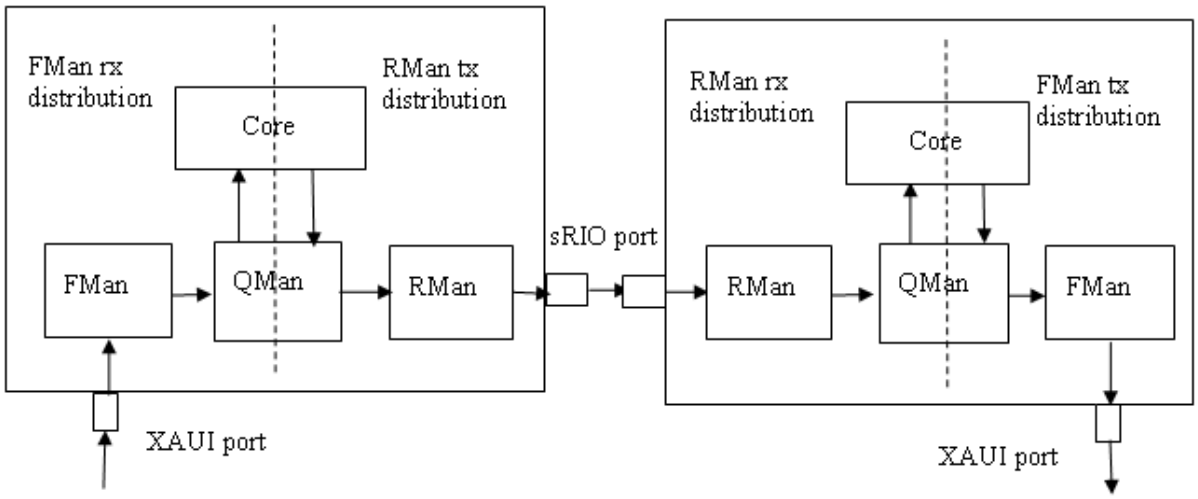

Figure 420. Packet Processing - Processing2

In the Processing2 flow, the FMan and RMan enqueue the packets to a frame queue of pool channel. Then, the core will dequeue and process the packets, and enqueue them to the FMan or RMan dedicated transmission channel to be sent out.

Procedure for FRA

1. Boot board in USDPAA mode
2. Execute the following commands on the board:

```
# cd /usr/etc
```

3. Configure PCD using the command:

```
# fmc -c usdpaa_config_p3_p5_serdes_0x33.xml -p usdpaa_policy_hash_ipv4.xml -a
```

   XML files can be found in the SDK. Use a different configuration file for each platform.

4. Launch FRA using the command:

```
# fra -c usdpaa_config_p3_p5_serdes_0x33.xml -p usdpaa_policy_hash_ipv4.xml -f
fra_config_dstr_processing1.xml
```

   FRA uses the following configuration files:

   - Packet processing using a data-streaming transaction:
     - `fra_config_dstr_processing1.xml`
     - `fra_config_dstr_processing1_port2.xml`
     - `fra_config_dstr_processing2.xml`
     - `fra_config_dstr_processing2_port2.xml`
     - `fra_config_dstr_port1_port2_loopback.xml`
     - `fra_config_dstr_testspeed_rxpoint.xml`
     - `fra_config_dstr_testspeed_txpoint.xml`
   - Packet processing using a mailbox transaction:
     - `fra_config_mbox_processing1.xml`
     - `fra_config_mbox_processing1_port2.xml`
     - `fra_config_mbox_processing2.xml`
     - `fra_config_mbox_processing2_port2.xml`

5. Launch TestCenter project to pump traffic, and the FRA is ready to receive traffic.
6. Create ‘Raw Stream’ in the generator for each port.
7. Compose a packet by changing the Mac/IP address and IPv4 Modifier Count according to your environment.

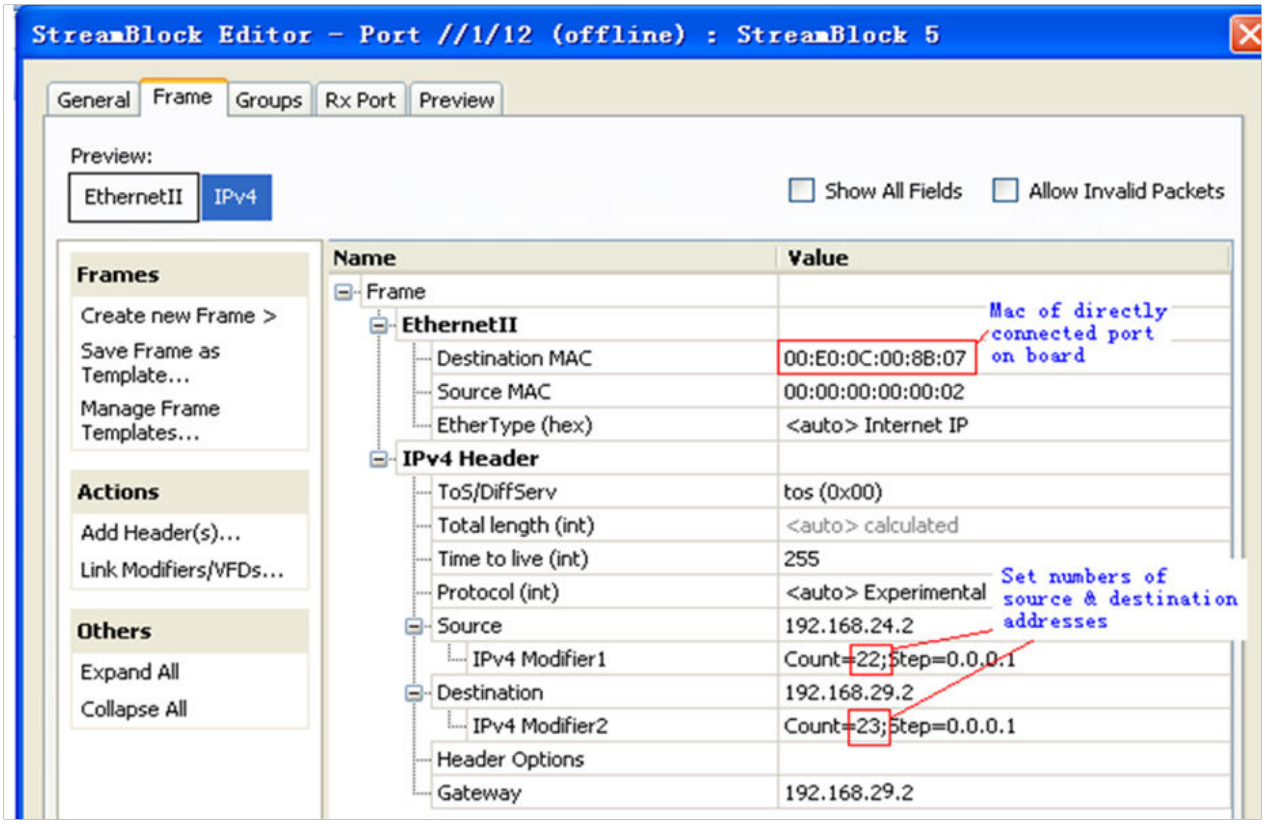

Figure 421. StreamBlock Editor

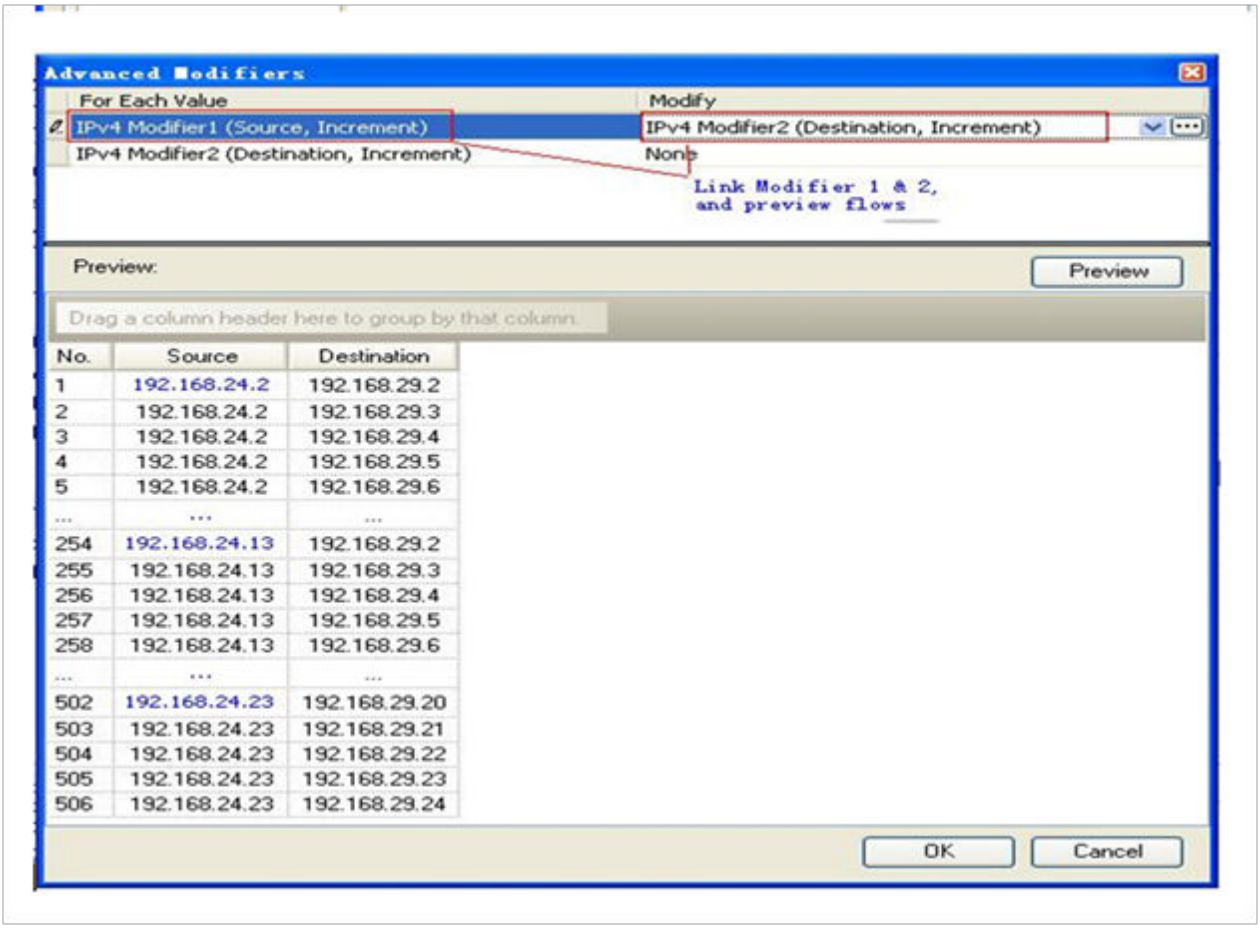

Figure 422. Advanced Modifiers

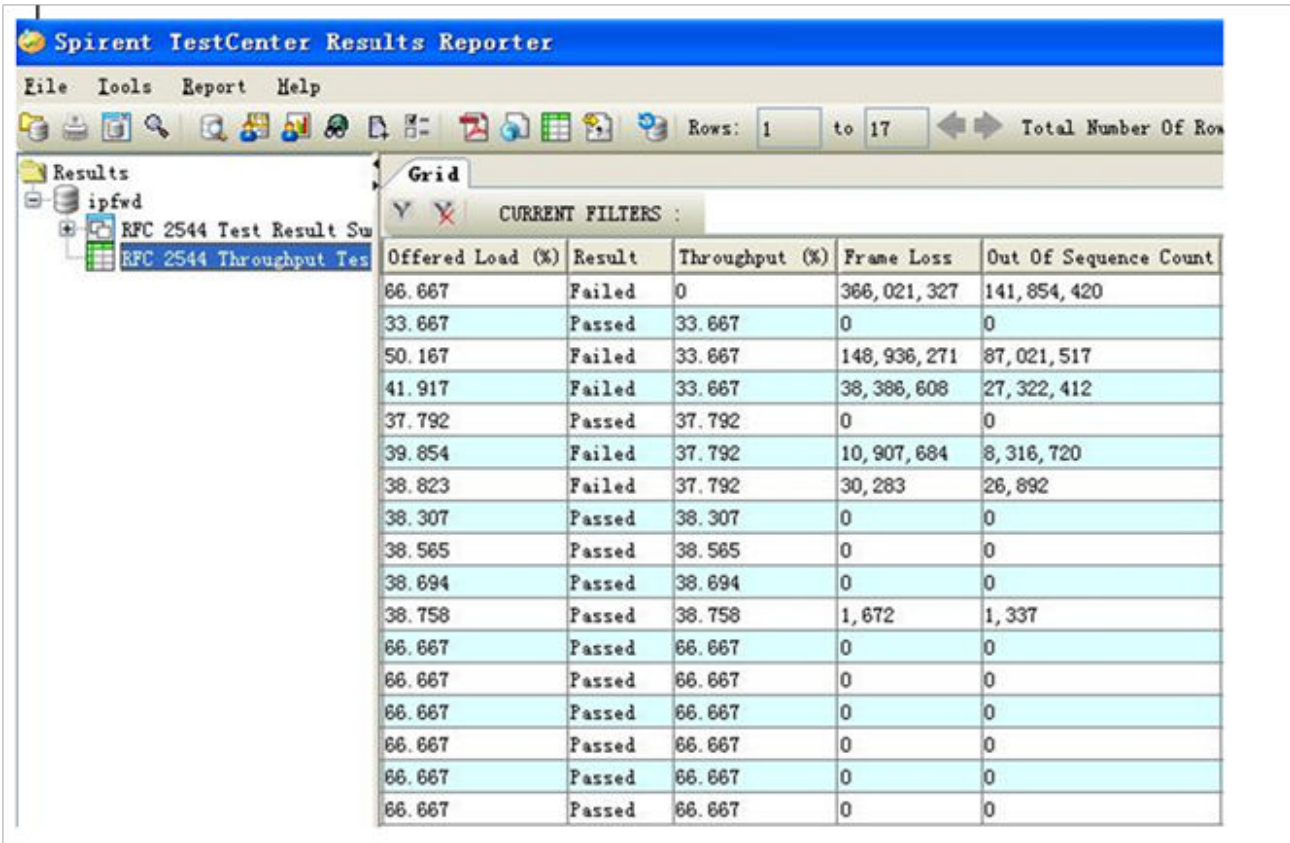
8. Create the 'Command Sequencer' in the Spirent TestCenter and select the 'RFC2544 Throughput' template.
9. Make the following variable settings:
   - Test Duration: 60 seconds
   - Resolution: 0.1%
   - Packet Loss Rate: 0.001%
   - Packet size: 64, 260, 1024 bytes
10. Start the Command Sequencer to measure performance.

12.3.4.4 View of Test Result

The following shows the results of the Test Center Results Reporter, when measuring the performance of the RFC 2544 Command Sequence:



Offered Load (%)	Result	Throughput (%)	Frame Loss	Out Of Sequence Count
66.667	Failed	0	366,021,327	141,854,420
33.667	Passed	33.667	0	0
50.167	Failed	33.667	148,936,271	87,021,517
41.917	Failed	33.667	38,386,608	27,322,412
37.792	Passed	37.792	0	0
39.854	Failed	37.792	10,907,684	8,316,720
38.823	Failed	37.792	30,283	26,892
38.307	Passed	38.307	0	0

12.3.5 sRIO

Instructions for executing benchmarking code for sRIO performance measurements of the P3041DS.

12.3.5.1 Introduction

Instructions for executing benchmarking code for USDPAA sRIO performance measurements.

The USDPAA sRIO performance benchmark is a specific instance from a suite of embedded SoC benchmarks. The goal of this exercise, summarized in the list below, is to provide the user with a range of performance options from which to select an SoC performance target that matches end product requirements.

The USDPAA sRIO performance benchmark can be implemented on the P2041/P3041/P4080/P5020/T4240/B4860 platforms. This document gives an instance of the steps based on the P3041 platform, although other platfroms may also refer to this document.

12.3.5.1.1 Platform Identification

Hardware Platform Identification

Depending on the platform, the application uses the setup shown in the table below.

Table 684. System Setup

Platform	Platform Rev.	Silicon Rev.	Default frequency Core/CCB/DDR/FMan	SerDes Protocol	Configuration Name
P2041RDB	Rev B	Rev 2.0	• CPU - 1500 MHz • CCB - 750 MHz • DDR - 1333 MHz • FMan - 583 MHz	0x09	RR_PX_0x09
P3041DS	Rev X1	Rev 2.0	• CPU - 1500 MHz • CCB - 750 MHz • DDR - 1333 MHz • FMan - 583 MHz	0x36	RR_HXAPNSP_0x36
P4080DS	Rev X3	Rev 3.0	• CPU - 1500 MHz • CCB - 800 MHz • DDR - 1300 MHz • FMan - 600 MHz	0xe	R_PPSXX_0xe
P5020DS	Rev X7	Rev 2.0	• CPU - 2000 MHz • CCB - 800 MHz • DDR - 1333 MHz • FMan - 600 MHz	0x36	RR_HXAPNSP_0x36
P5040DS	Rev X4	Rev 2.1	• CPU - 2266 MHz • CCB - 800 MHz • DDR - 1600 MHz • FMan - 600 MHz	0x02	RR_XXSNSpP_0x02
B4860QDS	Rev B2	Rev 2.1	• CPU - 1600 MHz • CCB - 667 MHz • DDR - 1867 MHz • FMan - 667 MHz	0x2A_0x8D	N_RSSS_0x2A_0x8D
T4240QDS	Rev X4	Rev 2.0	• CPU - 1667 MHz • CCB - 733 MHz • DDR - 1866 MHz • FMan - 733 MHz	1_1_5_5	RR_XXXXPRPR_1_1_5_5

Software Platform Identification: Host development System Software with the latest version

- QorIQ DPAA SDK 1.8 Release
- Compiler from SDK 1.5

- GCC v4.7.3, GLIBC 2.15
- Linux Kernel v3.8.13

12.3.5.1.2 Setting Up the Test Environment

Details of the operational variables and product characteristics for both the hardware and the software are presented. For information on the P3041 SoC and P3041DS board hardware configurations, please refer to:

- *P3041 Reference Manual*
- *P3041DS Reference Manual*

NOTE

The following instructions are specific to P3041DS, though this guide may also be used for other platforms.

Hardware Environment

The following figure shows a high-level hardware setup of the sRIO application.

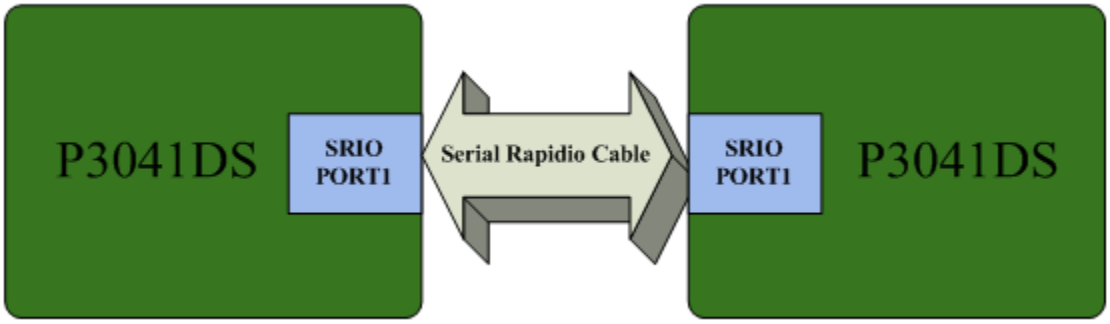

Figure 424. Test Configuration

Identifying the Hardware Version for P3041 platform

The details of the SoC and Board hardware are shown below:

Table 685. SoC Supported Hardware Configuration

Characteristic	Description
CPU Core	Rev 1.0, e500mc Core version 2.2
Cache	• L1: 32KB • L2: 128KB SPLRU with aging • CPC: 1MB SPLRU with aging
Operating Frequency	• CPU - 1500 MHz • CCB - 750 MHz • DDR3 - 667 MHz (1333 MT/s) • FMan - 583 MHz

Table continues on the next page...

Table 685. SoC Supported Hardware Configuration (continued)

Characteristic	Description
Board	P3041DS, Sys ID: 0x1c, Sys Ver: 0x01, FPGA Ver: 0x04
DDR3	DDR3 667MHz Asynchronous (transaction rate 1333MT/s) • 1T timing, No ECC • 2 Chip select cache line interleaving per controller.
Chip Select	Each covers 1024MB memory = total 2GB
Chip Select	Each covers 1024MB memory = total 2GB
SGMII Card	1 card with 3 Ethernet ports and 2 RGMII ports
XAUI	1 card
PCIe	1G NIC

Identifying the Software Platform Version

All software was built from SDK ISO. The details of the Software components are shown below:

Target Development System Software

The table below shows a description of each software components:

Table 686. Target Development System Software Detail

Component	Description
Boot loader	The U-Boot used is distributed with the SDK package.
RCW	The RCWs used is distributed with the SDK package. For sRIO test, Serdes 0x33 (1 XAUI ports, 2 sRIO ports and 2 RGMII port) is choosen: • rcw_0x33_1500mhz.bin
FMan ucode	The ucode used is distributed with the SDK package.
Kernel and dtb	Enable the RapidIO UIO driver and the DMA UIO driver in the kernel module configuration: Device Drivers --->\ <*> Userspace I/O drivers --->\ <*> Freescale Serial RapidIO support\ <*> Freescale DMA support
root filesystem considerations	The tests procedure for sRIO performance based on standard rootfile system.

12.3.5.2 Configuring and Running the Benchmark Test

NXP Serial RapidIO user space driver is based on NXP Linux SDK. It is composed of Linux UIO driver in Linux kernel space and sRIO driver/application in Linux user space. There are DMA and sRIO UIO drivers, which map DMA/sRIO registers and sRIO window to linux user space for user space driver usage. User space DMA and sRIO drivers provide driver interfaces for application, while timer driver provides means to measure the performance. Applications can use driver interface to accomplish the final srio function. Currently, the sRIO driver supports two rapidio ports, and the DMA driver supports two controllers and eight channels based on basic direct mode and basic chain mode . The demo SRA application can implement SRIO SWRITE, NWRITE, NWRITE_R, NREAD, ATOMIC_INC, ATOMIC_DEC, ATOMIC_CLR, ATOMIC_SET type protocols based on window/segment/subsegment, and give the user sRIO performance data to evaluate NXP rapidIO IP block.

12.3.5.2.1 Instructions for Booting Up

Table 687. Target Development System Software Detail

Step	Description
`setenv ipaddr=<board_ipaddress>`	Gives the board a static IP.
`setenv netmask=<netmask>`	Network masking required to contact the tftpserver.
`setenv serverip=<server_ipaddress>`	The IP Address of the tftp server.
`editenv bootargs`	USDPAA process driver accesses DMA memory. Append "usdpaa_mem=64M" to existing bootargs.
Deployment of the Linux kernel and File system to the P3041DS board.	
Login to the P3041DS board.	Use login ID = “root”

NOTE

For more information refer to each specific platform quickstart guide.

12.3.5.2.2 Test Commands and Scenarios

SRA (Serial RapidIO Application) Help

sra> sra
```

Then SRA help will display. Error command will cause SRA to print help information. Following are the help information:

```
-----------------SRIO APP CMD FORMAT-----------------
Set window attribute
sra -attr [port_id] [fun] [fun_id]([write_attr] [read_attr])
sra -attr port1/2 device_id [id]
sra -attr port1/2 target_id [id]
sra -attr port1/2 seg_num [num]
sra -attr port1/2 subseg_num [num]
sra -attr port1/2 subseg_tdid [seg_id] [tdid]
sra -attr port1/2 accept_all [id]
sra -attr port1/2 irq [id]
sra -attr port1/2 win_attr [id] [write_attr] [read_attr]
sra -attr port1/2 seg_attr [id] [write_attr] [read_attr]
```

```
Notes:
        [id] for command accept_all: 0 - disable; 1 - enable
        [id] for irq: 0 - disable; 1 - enable
                [write_attr]    : swrite/nwrite/nwrite_r
        [read_attr]     :
 nread/atomic_inc/atomic_dec/atomic_set/atomic_clr

Do sra operation
sra -op [port_id] [win_id] [seg_id] [subseg_id] [operation] [data_len]
sra -op port1/2 [win_id] [seg_id] [subseg_id] w/r/s/p [data_len]
        [data_len]      : should be less than the window/segment/subsegment's size, max size is 2M
                        data_len should be 1/2/4 for ATOMIC operation

Do SRIO test and print performance result
sra -test [case] [port] [task] [srio] [number]
 sra -test srio port1/2 dma/core [srio_type] payload_size
        [srio_type] should be swrite/nwrite/nwrite_r/nread
        payload_size should be less than 2M bytes
 sra -test dma_chain
 sra -test show_perf port1/2 times
 sra -test show_task
 sra -test free_task port1/2
-----------------------------------------------------
```

SRA Test Operation

This command uses sRIO port1 or port2 to implement RapidIO performance test, or do DMA basic chain mode test based on the [case] parameter input. In RapidIO performance test, if you just give the parameters [case], [port], [task], it will measure the sRIO performance under different transmission protocol type, with different transmission data size, and with different dma BWC (bandwith control), and print out the performance result. If you give all the parameters [case], [port], [task], [srio], [number], it will create a task for the specific sRIO transmission performance test. When you want to get the performance result from the task, you can start the calculation by the other command. In DMA basic chain mode test, SRA will copy lower region data to the upper region.

SRA Test under DMA mode

This will measure the sRIO port1 performance using DMA under different transmission protocol type with different transmission data size, and with different dma BWC (bandwith control). It will print out the performance result at the end.

```
sra> sra -test srio port1 dma
```

SRA Test under core mode

This will measure the sRIO port1 performance using core under different transmission protocol type with different transmission data size. It will print out the performance result at the end.

Note: The cache will impact the results of the performance.

```
sra> sra -test srio port1 core
```

SRA Test to create a transmission task with DMA mode

This will create a sRIO transmission task with the port1, DMA mode, the swrite protocol type, and the 4096 bytes payload size. It can print out the performance result for the specific transmission at the start of the performance calculation with the other command.

Note: The payload size should be less then 2M bytes.

```
sra> sra -test srio port1 dma swrite 4096
```

SRA Test to create a transmission task with core mode

This will create a sRIO transmission task with the port2, core mode, the nread protocol type, and the 2048 bytes payload size. It can print out the performance result for the specific transmission at the start of the performance calculation with the other command.

Note: The payload size should be less then 2M bytes, and the cache will impact the results of the performance.

```
sra> sra -test srio port2 core nread 2048
```

SRA Test for DMA chain

The SRA will implement the DMA chain mode test.

```
sra> sra -test dma_chain
```

SRA Test to start the task's performance calculation

When there is a sRIO task on port1, this command can start the performance calculation with the 10000 transmission times. And it will print out the performance result at the end.

```
sra> sra -test show_perf port1 10000
```

SRA Test to show the existing tasks

When there are sRIO tasks, this command can show the all tasks on port1 and port2, and print out the task's parameters.

```
sra> sra -test show_task
```

SRA Test to free the task

When there is a sRIO task on port1, this command can free the task.

```
sra> sra -test free_task port1
```

12.3.5.2.3 Running the Test

After two boards boot up, login to Linux and run the test commands in the Test Command and Scenarios section, so you can implement the sRIO performance. The figure below gives a more detailed description for the NWRITE/NREAD transactions.

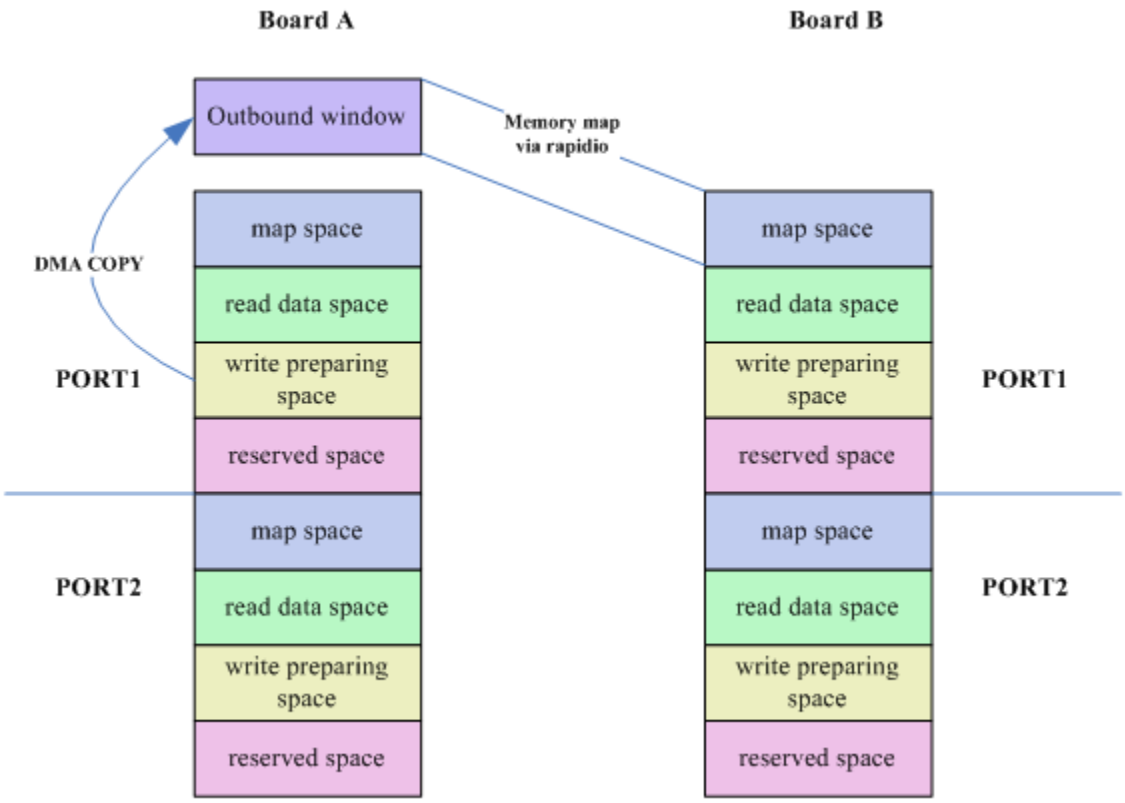

Figure 425. SRIO NWRITE Operation with Two Boards

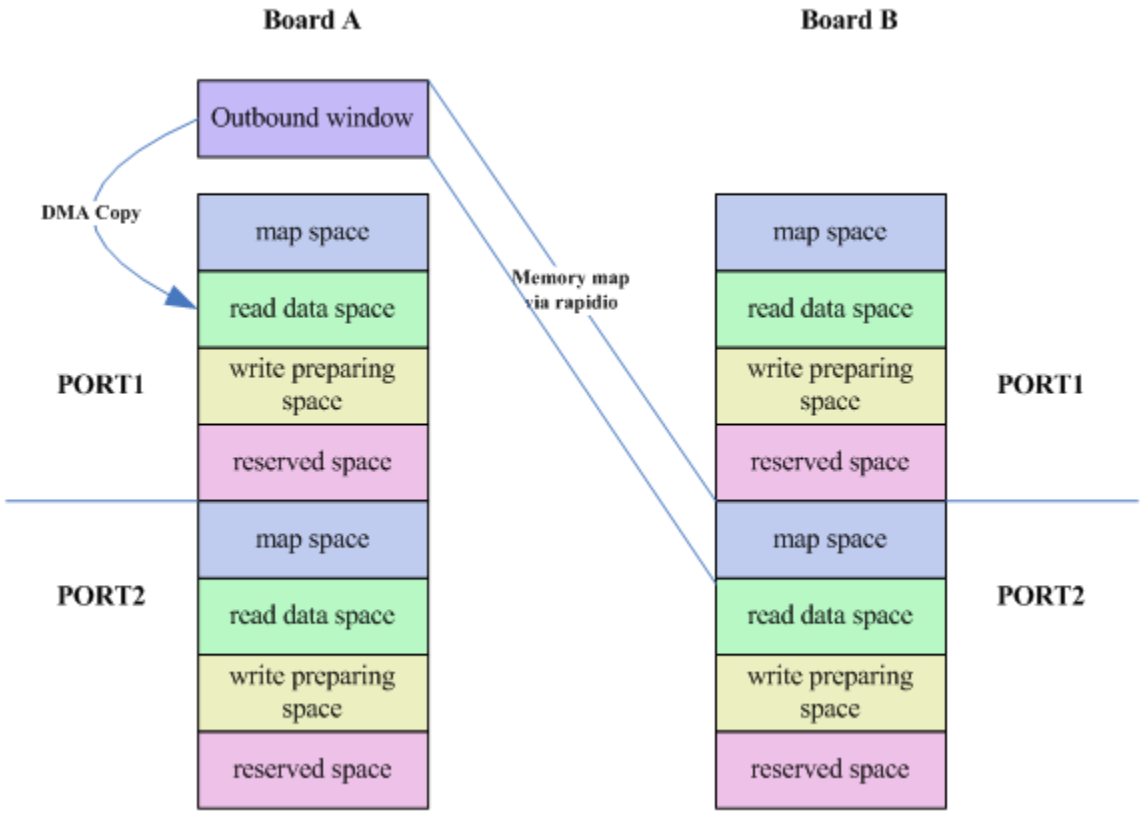

Figure 426. SRIO NREAD Operation with Two Boards

12.3.5.3 Test Result Analysis

The expected result is best when benchmarking is performed from the 1 DMA 1 exclusive channel configuration.

Theoretical Data Throughput:

The maximum transfer rate is 10 Gbps (3.125Gbps link rate, 4x, each direction, after 8B/10B encoding).

sRIO Protocol Efficiency

Table 688. sRIO Protocol Efficiency

Transaction Type	Payload	Overhead	Efficiency
SWRITE	256 Bytes	18 Bytes	93.4%
NWRITE / NWRITE_R	256 Bytes	20 Bytes	92.8%

Theoretical Payload Throughput Calculation:

sRIO Payload Throughput = (Theoretical Data Throughput) x (sRIO Protocol Efficiency)

- NWRITE / NWRITE_R = 10G x 92.8% = 9.28 Gbps
- Assumes 100% Line Utilization
